CLINICAL AND EXPERIMENTAL

HEART DISEASE AND LIVER FUNCTION*

Mitchell Bernstein, M.D., Edward B. Le Winn, M.D., and Samuel Simkins, M.D., Philadelphia, Pa.

HERETOFORE, studies of the relationship of hepatic function to heart disease have been based solely upon clinical observations.[1-5] A review of the literature fails to disclose any studies correlating liver function and cardiac disease, as determined by precise methods. In the present report we have attempted to study this relationship by means of the bromsulfalein retention test and by the measurement of the velocity of blood flow and the venous pressure.

MATERIAL AND METHODS

A group of 59 patients, free from hepatobiliary disease was studied. There were 29 men and 30 women, ranging in age from 19 to 79 years. These patients were studied clinically and quantitatively as to the status of the circulation and liver. For the purpose of this investigation the patients were divided as follows:

A. *Control Group:* Patients free from any demonstrable evidence of heart disease. Five patients with uncomplicated hyperthyroidism were included in this group.

B. *Cardiac Group:* These patients, evidencing definite heart disease, were for practical purposes[6] subdivided on a functional basis as follows:

1. Fully compensated heart disease.
2. Mild cardiac decompensation, evidenced by exertional dyspnea and cyanosis.
3. Moderate cardiac decompensation, evidenced by dyspnea, cyanosis, and pulmonary congestion, the last named being demonstrable clinically or by roentgen-ray examination.

---

*From the Medical Service of Mitchell Bernstein, M.D., Jewish Hospital, Philadelphia.
Received for publication, April 11, 1942.

4. Marked cardiac decompensation, evidenced by symptoms and signs of groups 2 and 3 plus hepatomegaly, edema, or ascites. Three patients were listed in more than one group in accordance with their changing functional cardiac status.

In the group of cardiac patients were 14 with hypertensive cardiovascular disease, 16 with arteriosclerotic heart disease, 5 with myocardial infarction, 6 with rheumatic heart disease, 2 with subacute bacterial endocarditis, and one with adhesive pericarditis.

The circulation was studied quantitatively by means of the venous pressure and the magnesium sulfate and ether circulation time tests. The venous pressure was measured directly by the use of an L-tube, calibrated in millimeters and centimeters, to which was attached an 18 gauge needle. Both tube and needle were thoroughly flushed with 2.5 per cent sodium citrate solution. The patient was in recumbent position, except when prevented by extreme cardiac insufficiency. The arm was abducted to a 45 degree angle and supported on a pillow which was so arranged as to place the antecubital fossa 5 cm. posterior to the level of the fourth sternochondral junction. A tourniquet was applied to the arm, and the needle was inserted into a large antecubital vein. The patient was cautioned to lie and breathe as quietly as possible. After the fluctuations of the venous column of blood subsided, the pressure was read directly in centimeters of blood. With the needle left in situ 5 c.c. of warm 10 per cent magnesium sulfate solution were injected as rapidly as possible and the end point was determined, giving the arm-to-tongue circulation time. One minute later 5 minims of ether mixed with 5 minims of normal saline solution were injected and the end point was determined, giving the arm-to-lung circulation time.

By means of the bromsulfalein retention test an index of the liver function was obtained. A dose of 5 mg. of bromsulfalein per kilogram of body weight was employed. The bromsulfalein determination followed or preceded the study of the circulation as closely as possible, usually within one or two hours. After injection of the dye, readings were made from specimens of blood collected at intervals of five, fifteen, and thirty minutes.

A total of 70 sets of circulation times, venous pressure, and bromsulfalein determinations were performed in the 59 patients.

Criteria.—The following values were used as normals in determining the status of the circulation:

Venous pressure: 3 to 12 cm. of blood.

Arm-to-tongue circulation time (magnesium sulfate circulation time[6]) eight to fourteen seconds.

Arm-to-lung circulation time (ether circulation time) three to eight seconds.

Lung-to-tongue circulation time (magnesium sulfate circulation time minus ether circulation time) up to eight seconds.

Failure of the left side of the heart was evidenced by a reading of lung-to-tongue circulation time greater than eight seconds. Failure of the right side of the heart was evidenced by a reading of ether circulation time greater than eight seconds and/or by a reading of the venous pressure over 12 cm. of blood.

Bromsulfalein retention of 10 per cent was considered as the upper limits of normal.

RESULTS

A. *Control Group.* Fifteen sets of determinations were performed on 15 noncardiac patients. In 14 patients the bromsulfalein liver function test was normal, whereas one patient showed an abnormal bromsulfalein retention without demonstrable cause.

B. *Cardiac Group.*—In 10 patients comprising group 1 (fully compensated heart disease), 12 of 13 determinations made showed agreement and one determination showed disagreement between the cardiac status and the liver function. Group 2, consisting of 10 patients, disclosed 11 determinations in which there was agreement and 3 with disagreement. Of 14 determinations made on 14 patients in group 3, 6 determinations showed the cardiac status and the liver function tests to be in agreement and 8 showed disagreement. In group 4, consisting of 13 patients, 11 of 14 determinations showed agreement between the cardiac status and liver function, whereas 3 showed disagreement.

Three cases are worthy of special mention. One patient, a 63-year-old man with acute myocardial infarction, at first disclosed failure of the right and left sides of the heart, as evidenced by the circulation time. There was marked cyanosis which persisted throughout a prolonged convalescence. Although the magnesium sulfate circulation time decreased steadily from 25.4 seconds to 14.4 seconds within a period of twenty-two days, with a corresponding drop in ether circulation time from 16.0 to 7.6 seconds, the parallel bromsulfalein determination ranged from 40 per cent to 28 per cent retention. It is very probable that the anoxemia, as evidenced by the cyanosis, may have been a causal factor in the continuance of the abnormal bromsulfalein retention. Another patient, a 60-year-old woman with decompensation due to hypertensive cardiovascular disease, showed exceptional parallelism between the liver function and the cardiac status as the state of compensation progressively improved, both clinically and by the method of measurement described above. A third patient, a 52-year-old woman with rheumatic aortic stenosis complicated[s] by hyperthyroidism, showed slight abnormal bromsulfalein retention (12 per cent) with moderate failure of the right side of the heart; venous pressure 14.8 cm.; arm-to-tongue (magnesium sulfate) circulation time 15.8 seconds; and arm-to-lung (ether) circulation time 10.6 seconds. It is to be noted in the foregoing case that the circulation times would undoubtedly have been much higher were it not for the marked tendency of the hyperthyroidism to decrease the circulation time.

DISCUSSION

Our studies indicate that the bromsulfalein excretion is normal in the absence of heart failure (control and compensated heart disease groups). In mild degrees of cardiac failure (group 2) the bromsulfalein excretion is impaired in close parallelism with the status of the circulation. Incidentally, it is worthy of mention that in mild degrees of cardiac decompensation the circulation times and venous pressure may fall within normal limits in a fairly high percentage of patients, a fact previously brought out by the authors.[6]

It is noteworthy that in patients with definite pulmonary congestion (group 3) the correlation of hepatic function with the condition of the circula-

A SIMPLIFIED BEDSIDE TEST FOR LATENT JAUNDICE*

Alan Leslie, M.D., New York, N. Y.

An ordinary, thin, 3 inch rubber band is the only apparatus required for this test, the technique of which is as follows: The rubber band is placed about the patient's upper arm, drawn taut mesially away from the skin, and then released. A typical "triple response" of Lewis[1] then takes place. We are not concerned with either the red reaction or the flare. A wheal (third phase of the "triple response") appears in five to fifteen minutes. The surrounding skin is then stretched in order to blanch the area, which is the site of the erythematous flare. This may be done advantageously by pressure over a glass slide. The colors of the wheal and of the surrounding skin are compared in either day or artificial light, the former being preferred. A positive test for jaundice is characterized by yellow coloration of the wheal.

The physiologic principles underlying the test have been well known for considerable time. In 1931 Klein[2] demonstrated that in cases of jaundice wheals produced by the intracutaneous injection of histamine were darker yellow than the surrounding skin. He further stated that when the bilirubin content of the blood was raised to levels insufficient to produce clinically detectable jaundice, histamine wheals showed yellow coloration. In 1936, Brodribb and Cullinan[3] reported quantitative studies of this method. They injected 0.1 mg. of histamine in 1 minim of sterile solution intracutaneously in the upper arm or back. They were able to detect a yellow coloration of the wheal in cases of biliary obstruction or hepatic damage when the blood bilirubin was 0.5 mg. or more per 100 c.c. In cases of hemolytic jaundice positive tests were not seen unless the blood bilirubin concentration was at least 1.1 to 1.4 mg. per 100 c.c. These authors mentioned the possibility of positive tests in carotinemia and allied diseases in which there is increased pigment in the blood.

The wheal of the "triple response" of Lewis, which is due perhaps to liberated histamine or "H-substance," is physiologically indistinguishable from

wheals produced by histamine injected intracutaneously. Any brisk superficial localized trauma may be substituted for the rubber band method of raising the wheal, but because of its simplicity and convenience, this latter procedure is specifically recommended.

OBSERVATIONS ON ADDITIONAL INSTANCES OF A SUPERNORMAL PHASE IN THE HUMAN HEART*

Howard B. Burchell, M.D., Rochester, Minn.

In 1924 Lewis and Master[1] reported a case of heart block in which complete dissociation of the auricles and ventricles was interrupted by occasional conducted beats. It was noted that in order for conduction from auricle to ventricle to occur, the P wave had to fall in a definite time period after the preceding QRS complex of the idioventricular rhythm. Cases of this type are not rare, and an example (Case 1) has been chosen from two which I have encountered.

REPORT OF CASES

Case 1.—The patient was a man 73 years of age who suffered from attacks of syncope. Except for bradycardia and generalized senescent changes, physical examination gave negative results. An electrocardiogram (Fig. 1) revealed an idioventricular rhythm with a cycle of two seconds, and occasional interruption or interference of the cycle by premature ventricular complexes which followed a P wave with a constant P-R interval. When the P waves which were followed by ventricular complexes were charted (Fig. 2), it was seen that they fell between 0.56 and 0.88 second after onset of the preceding QRS complex; P waves falling outside this phase were not conducted.

Comment.—Lewis and Master explained this phenomenon by the presence of a supernormal phase of conductivity similar to a biologic phenomenon observed by Adrian and Lucas[2] in 1912 and described in greater detail by Adrian[3] in 1921. These observers demonstrated that in injured, excitable tissue there was a short period during recovery from a previous stimulus in which the tissue became hypersensitive to new stimuli. In 1925 Ashman[4] observed the existence of the supernormal phase of conductivity in the hearts of turtles, in which varying degrees of auriculoventricular block had been produced. The work of Hoff and Nahum[5] in 1938 indicated that a supernormal phase of excitability could be present in relatively normal mammalian ventricular muscle.

A second type of cardiac mechanism exhibiting evidence of the supernormal phase is much more rare and is that of paroxysmal heart block occurring con-

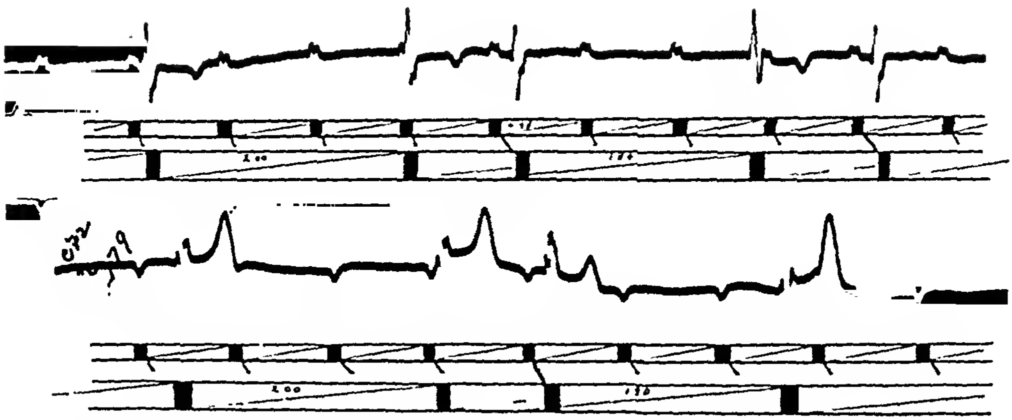

Fig. 1.—Complete heart block except for occasional auriculoventricular conduction. Two conducted beats are shown in the upper tracing (Lead II) and one in the lower tracing (Lead CF_2). The ventricular complex of the conducted beat has a different shape from the QRS complex of the idioventricular rhythm. It is also interesting to note that the returning cycle of idioventricular rhythm is shorter than might be expected.

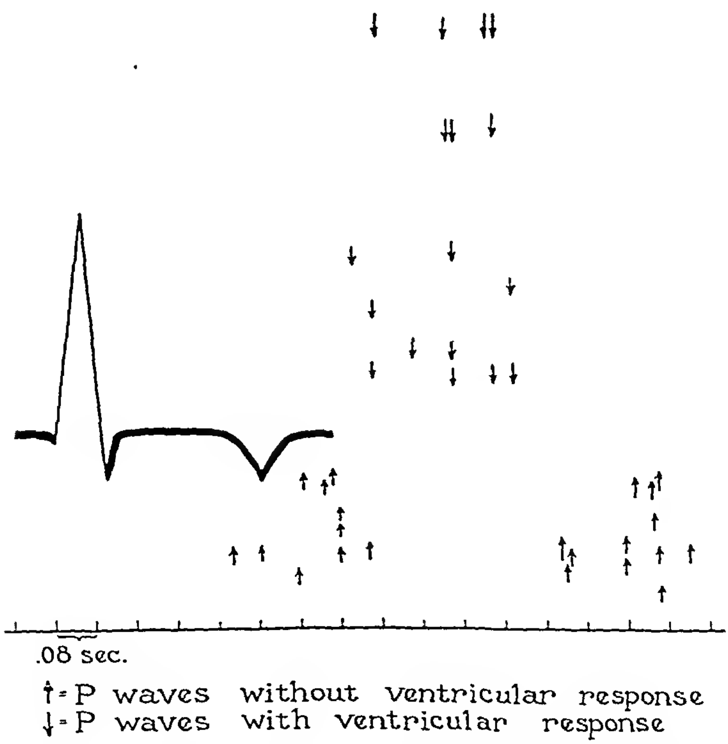

Fig. 2.—The positions of all the P waves that were followed by auriculoventricular conduction are compared with the positions of P waves associated with auriculoventricular block. There is a slight overlapping of two groups at the beginning of the time phase of favored conductivity, but not at the end of this phase. The P-R interval of the conducted beats is not charted but was normal and the same for all conducted beats.

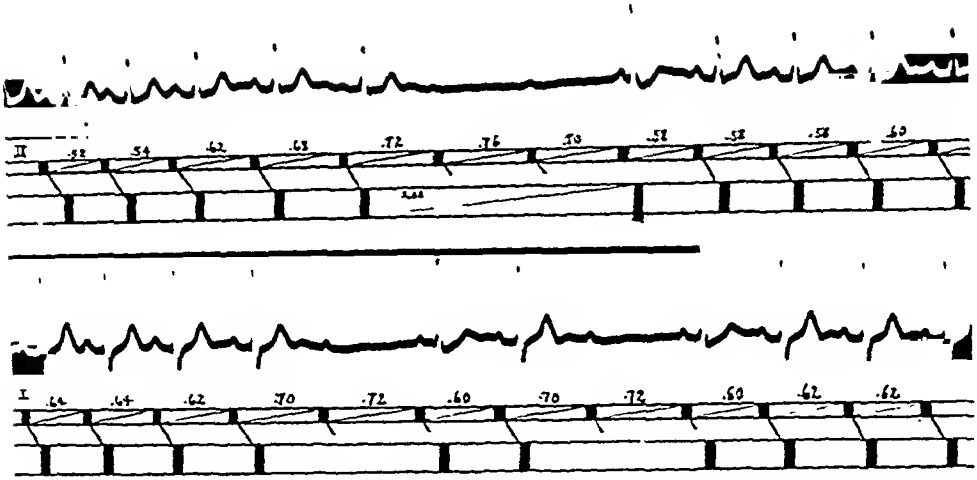

Fig. 3.—Paroxysms of complete auriculoventricular block following auricular slowing and resumption of auriculoventricular conductivity only when a P wave has fallen in a definite time relationship after an idioventricular beat are demonstrated. The phenomenon may be seen once in the upper tracing and twice in the lower. The P-P intervals are given in hundredths of seconds.

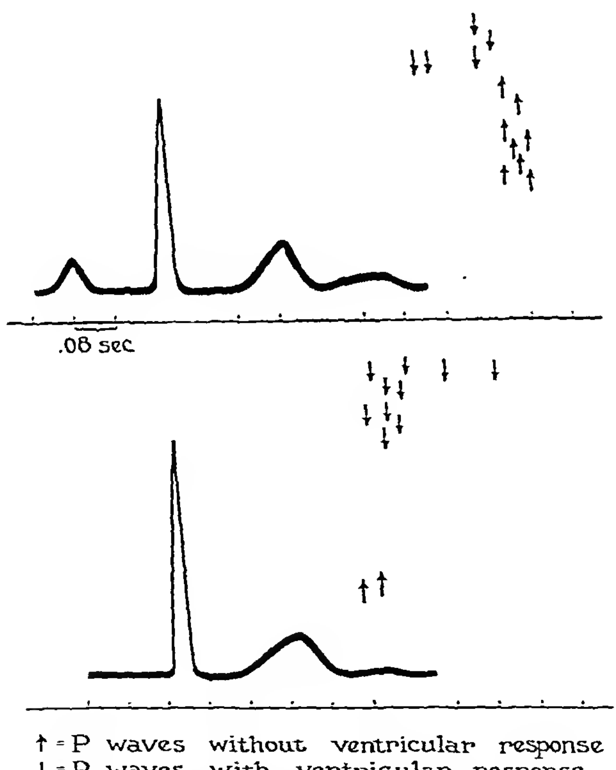

Fig. 4.—Upper portion demonstrates the position of P waves, always followed by auriculoventricular conduction and the maintenance of normal rhythm, and the position of P waves followed by auriculoventricular block. In the original tracing numerous P waves were present, but as they all had the same grouping, many were omitted in this figure as their numbers added nothing to a smaller representative group. In the lower portion of the chart P waves which followed an idioventricular beat and were associated with auriculoventricular conduction and the resumption of normal rhythm may be seen. Except for one possible exception P waves outside this time relationship were not associated with auriculoventricular conduction.

comitantly with auricular slowing. The electrocardiographic records obtained in Case 2 are similar to those obtained in a case reported by Wilson and Herrmann[6] and described later in detail by Ashman and Herrmann,[7] and to those in a case reported by Kline, Conn, and Rosenbaum.[8]

CASE 2.—The patient, a man 29 years of age, registered at the Mayo Clinic in February, 1940, and related a history of frequent attacks of syncope of two years' duration. It was noted on physical examination that the fainting spells were associated with ventricular asystole and that attacks could be reproduced by pressure on either of the carotid sinuses. There was a rather distant, harsh, aortic systolic murmur, and the heart was slightly enlarged by roentgenographic examination. History of rheumatic fever was not obtained.

On electrocardiographic study it was noted that complete auriculoventricular dissociation was dependent on auricular slowing. Auriculoventricular conduction was never re-established until one or more idioventricular beats had occurred, and the P wave of the first beat to be conducted had to have a definite time relationship to the preceding QRS complex. The tracings reproduced in Fig. 3 are representative of numerous records obtained, both in spontaneous attacks of auriculoventricular dissociation and in attacks induced by pressure on a carotid sinus. In the upper tracing reproduced in Fig. 3 it may be seen that there is a gradual slowing of the auricular rate, the cycle increasing from 0.52 to 0.76 second, with a gradual displacement of the P wave away from the preceding complex. It was noted that as soon as the P wave falls away from the U wave phase of the tracing, conduction to the ventricle no longer occurred. In the lower tracing of the same figure the same phenomenon occurs twice. It may be pointed out again that there was no resumption of the normal rhythm until an idioventricular beat has occurred, that is, an idioventricular beat had to sensitize the conducting tissues from below before an auricular impulse could be conducted from above. When the P waves were charted (Fig. 4), it was found that when they fell more than 0.68 second after the preceding QRS complex auriculoventricular dissociation occurred. With return of auriculoventricular conduction the P waves fell between 0.40 and 0.65 second after the preceding QRS complex except for the one exception charted. That a vagal influence on the conduction mechanism is unlikely, is indicated by the fact that temporary resumption of conduction may occur while the auricular rate is still slow. An explanation dependent on an increased blood supply to the bundle following a period of block does not prove satisfactory, since the time of conducted beats is independent of the periods of ventricular standstill. The outstanding difference between this case and the usual case of Adams-Stokes' attacks dependent on paroxysmal heart block is that in the latter, heart block usually is preceded by an increase in the auricular rate and failure of recovery in the conducting tissues.

Since the patient had frequent attacks of syncope, digitalis was administered in the hope that it might produce permanent auriculoventricular block and relieve the symptoms. It was found, however, that digitalis caused complete block only when symptoms of mild intoxication from digitalis were present. Administration of digitalis, therefore, was discontinued. After the patient returned home, the symptoms soon disappeared entirely, and he was able to do his routine work on the farm.

The patient returned to the clinic two years later, in February, 1942. It was found that he had complete auriculoventricular dissociation with a ventricular rate of 40. Subcutaneous administration of 1 c.c. of epinephrine (1:1,000) or 1/50 grain (0.0013 Gm.) of atropine did not have any effect in changing the complete block. His general condition at this time was excellent, although the aortic systolic murmur was louder, a faint diastolic murmur was present at the left of the sternum and the heart had increased slightly in size. During a continued period of auscultation the first heart sound occasionally had the accentuated loudness characteristic in certain cases of complete heart block.

SUMMARY

The presence of the supernormal period in the human heart has been used to explain cases of interference dissociation in which the auricles are beating

more rapidly than the ventricles, cases of paroxysmal heart block in which cessation and resumption of auriculoventricular conduction have a phasic dependency on the immediately preceding electrical events and cases of possible parasystolic rhythm. An example is given of each of the first two types of mechanism which are best explained by the existence of a supernormal period in excitability of the conduction tissues. Case 2 is considered of some importance, as it is another instance of the undoubtedly rare cases in which the supernormal period has played a role in the maintenance of normal sinus rhythm. Following establishment of complete block, the patient has remained in relatively good health for two years.

PERCUTANEOUS TYPHOID PROPHYLAXIS*

ABRAHAM GELPERIN, M.D., M.P.H., AND DALE KESSLER, M.D.
CINCINNATI, OHIO

PERIODIC typhoid prophylaxis is necessary if there is continuous possibility of contact with the typhoid bacillus. Reinoculation by the intradermal route presents a technique that has promise of being the method of choice.[1] Since large numbers of persons are sometimes involved, it was deemed advisable to study the percutaneous route of administering antigenic stimulation in an attempt to simplify the procedure further.

It has been shown that many diverse substances are absorbed through the skin.[2, 3] In previous investigations huge doses of bacilli were utilized—as much as 100 mg. of bacilli by weight with an emulsion base.[4] Since such enormous amounts of antigen would be impossible of production, doses were used which seemed likely to be both antigenic and feasible of manufacture.

The typhoid strain utilized was isolated in 1926 at the Cincinnati General Hospital. Its Vi content is unknown. Standard vaccine was prepared, two billion bacilli to the cubic centimeter. The production of "H" antibodies was studied, since a measure of protective antibodies was not possible; and the production of "O" antibodies following intradermal inoculation was found to be

practically nil by Van Gelder.[5] Our titration of "O" antibody gave the same result. Our first attempt at percutaneous stimulation utilized 20 billion typhoid bacilli a day for three consecutive days; the second employed a single dose of 200 billion bacilli.

Twenty-four patients of the Hamilton County Chronic Disease Hospital, who had no history of either typhoid fever or prophylaxis, were divided into three groups. Initially each patient received an intracutaneous primary antigenic stimulation of 0.1 c.c. of the prepared vaccine. The control group, A, was reinoculated fourteen days later with 0.1 c.c. intracutaneously. Group B at the same time vigorously massaged an emulsion of 20 billion disintegrated (alternate freezing and melting) bacilli into the skin of the forearm, and group C an equal dose of whole bacilli. The emulsions were applied to alternate forearms for three consecutive days. The base was Jergens lotion, and each 0.2 c.c. contained the required dose.

Nine days after the termination of the secondary antigenic stimulations, blood sera titrations revealed equivocal results in groups B and C, and increases in 5 of 7 persons in group A. Six months later 13 patients were retested, 2 from group A, 7 from group B, and 4 from group C. (The other patients were not available.) The initial serum titrations showed marked losses in all. Each patient vigorously massaged an emulsion of olive oil and whole bacilli into the forearm; each 0.2 c.c. dose contained 200 billion bacilli. Sixteen days later serum titrations revealed no significant increases in titer.

With the technique employed, no appreciable typhoid "H" antibody was stimulated by percutaneous vaccination.

ACQUIRED DRUG RESISTANCE IN THE HEMOLYTIC STREPTOCOCCUS*

Morgan Cutts, M.D., and Albert V. Troppoli, Sc.M.
Providence, R. I.

MAC LEOD and Daddi,[1] and subsequently Lowell and co-workers[2] showed that some strains of pneumococci, previously susceptible to the action of sulfapyridine, can be rendered "resistant" by growing them in gradually increasing concentrations of the drug in vitro. Recently Hadley and Hadley[3] reported somewhat similar results in the case of a group A hemolytic streptococcus. Using increasing concentrations of sulfanilamide and an incubator temperature of 40° C., they were able to show an "adaptation" of the organism from 2.5 to 10 mg. per 100 c.c. drug concentration. They also noted a change from the mucoid to the smooth phase coincidentally with this adaptation. The present work was planned to investigate the production of drug resistance in vitro in the case of the hemolytic streptococcus, the association of phase transformations, and the duration and stability of the resulting modified strains.

The organism used throughout these experiments was a group A hemolytic streptococcus, freshly isolated from a case of acute pharyngitis. Culture media included plain blood agar plates without added peptone and a meat infusion broth of pH 6.8 likewise without added peptone. At one point in the experiments 20 per cent ascitic fluid was added to the standard broth to produce an enriched medium. The varying concentrations of the drug were obtained by adding the proper amounts of stock solutions of 50 or 100 mg. per 100 c.c. of sulfanilamide in broth.

In describing the various phases of the strains studied we have followed closely the outline of Dawson, Hobby, and Olmstead.[4]

At the outset considerable difficulty was encountered in selecting a suitable organism, for most strains whether freshly isolated or from stock cultures were little affected by concentrations up to 50 mg. per 100 c.c. of sulfanilamide in broth even when a small amount of inoculum was used. Finally the one used, GA, was found on repeated tests to show no growth in concentrations above 7.5 mg. per 100 c.c. sulfanilamide in broth. Morphologically, this organism closely resembled the other strains previously discarded. It formed small rounded colonies on blood agar whitish to reflected light with milky centers and no mucoid border and with a smooth margin when examined under low power. It formed homogeneous suspensions in saline and was not virulent for mice. The lethal dose was between 1 and 2 ml. of a twenty-four-hour broth culture. No capsules could be demonstrated. It resembled the typical "smooth" colony described by other workers. During the course of subsequent experiments it remained essentially stable, and only during the latter

*From the Charles V. Chapin Hospital, Providence.
Received for publication, April 13, 1942.

half did it show some tendency toward the M-S form, as evidenced by slightly increased size and flatness of the colony on blood agar, and by the occasional development of a mucoid "fringe."

Over a period of two weeks GA was subjected to growth in increasing concentrations of sulfanilamide in broth at a temperature of 37.5° C. This was begun at a concentration of 2 mg. per 100 c.c. and carried up by daily subcultures to a concentration of 100 mg. per 100 c.c. The resulting strain labeled GAR after being grown for several transfers in plain broth was tested for drug susceptibility at the same time as the parent strain GA which had meanwhile been carried in plain broth. The inoculum was small, i.e., one standard loopful of a twenty-four-hour broth culture was mixed with 5 c.c. of broth and a loopful of this mixture was used for the test. The results appear in Table I.

TABLE I

INITIAL COMPARISON OF DRUG RESISTANT AND ORIGINAL STRAIN

DRUG CONCENTRATION		0	5	7.5	10	15	20	25	35	50	75	100
GA	Broth	##	#	0	0	0	0	0	0	0	0	0
	Agar*	##	#	0	0	0	0	0	0	0	0	0
GAR	Broth	##	##	##	##	##	##	##	##	##	#	0
	Agar*	##	##	##	##	##	##	##	##	##	##	0

*Subculture from the corresponding broth tube after forty-eight hours. ##, Full growth: #, scant growth; 0, no growth.

The broth tubes were read at forty-eight hours, the agar plates at twenty-four hours.

As is evident a marked degree of drug resistance had been produced in GAR. Coincidentally with this, the phase of the organism had been changed, for GAR showed definite differences from the parent strain GA with regard to the colonies on blood agar plates. Comparing the two, GAR was smaller, had a finely stippled surface, and showed some roughening of the border, especially after forty-eight hours. GAR also showed some tendency to spontaneous clumping in saline suspensions as compared to none in GA. From this we inferred that GAR was in an intermediate stage between smooth and rough, an S-R form, while GA had remained smooth. This difference persisted and was even somewhat accentuated at the end of the experiments.

One month later GA and GAR were again tested, neither strain having been exposed to sulfanilamide in the interval. The findings were essentially the same as in Table I, the difference in susceptibility of the two strains to the drug being slightly more marked than before. An attempt was now made to modify the phase of GAR by growing it in enriched media. Twenty per cent ascitic fluid broth was used. The result was another variant, called GARA, which resembled the smooth type of organism in its colonial form except that unhemolyzed red blood cells were usually present immediately beneath the colony. Six weeks, and again three months, after the second test of GA and GAR all three strains were tested at the same time. The results of these and the original tests were represented in Chart 1.

At the close of these experiments GA was morphologically in the S or M-S phase, GARA was similar except for the unhemolyzed red blood cells beneath

the colony as noted before, and GAR was a definite S-R form very distinct in its colony type from either of the others. It is evident, therefore, that over a period of three months there was, in the case of GAR, a marked loss of resistance to sulfanilamide without any reversion to the standard or smooth type of this organism. It is also evident that in the case of GARA change of phase did not alter the susceptibility of the organism to sulfanilamide or cause any quicker loss of resistance to the drug than was the case with the parent strain GAR.

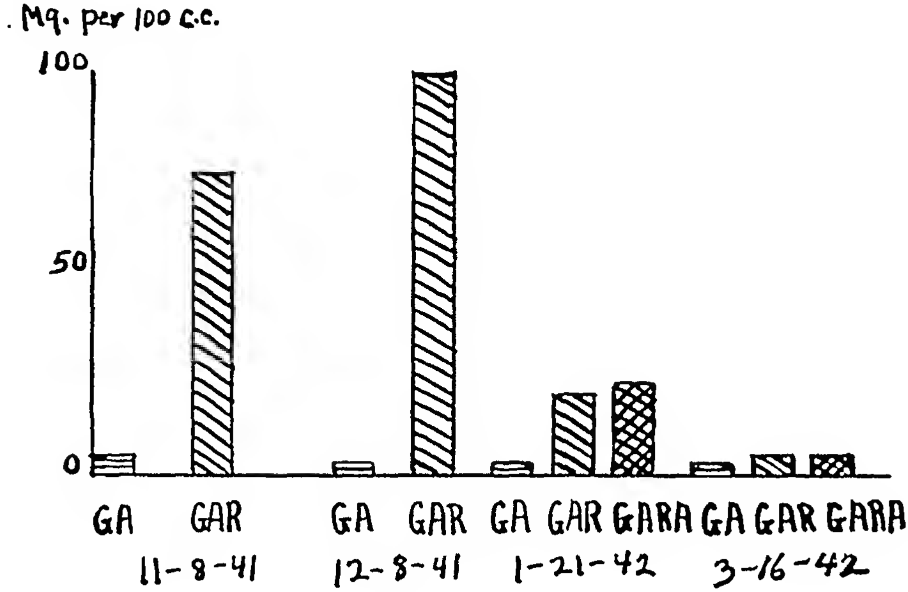

Chart I.

SUMMARY

1. A high degree of resistance to sulfanilamide was produced in vitro in a group A hemolytic streptococcus.

2. This resistance was maintained at a high level for one month and subsequently spontaneously disappeared in the course of about three more months.

3. Evidence is presented which suggests that though change of phase and drug resistance may be produced simultaneously by the action of sulfanilamide these two factors are not dependent upon each other, and may be separately modified.

CLINICAL EXPERIENCES WITH A MODIFICATION OF THE TAKATA REACTION IN BLOOD AND CEREBROSPINAL FLUID

H. Ucko, M.D., London, England

In 1935 and 1936 I described a modification of the Takata serum reaction. This reaction had been advocated as a test for the diagnosis of liver diseases by Staub (1929) and Jezler (1929). The modified test, which I studied in 160 cases, has since been investigated by a number of workers in different countries. They have tested the sera of more than 2,500 patients suffering from different morbid conditions, including a large number of pathologic conditions of the liver. In the Italian literature the test is generally referred to as "Ucko reaction." It has also been applied *to the cerebrospinal fluid of patients* suffering from organic diseases of the nervous system and has given interesting results in comparison with other protein reactions. It seems, therefore, worth while to survey the experiences of these authors, some of which are published in journals not available in this country and which give sufficient data to judge the diagnostic value of the test. This is the purpose of this paper.

TECHNIQUE AND NATURE OF THE MODIFIED TEST

The reaction consists in a precipitation of serum protein by addition of sodium carbonate and mercuric chloride to serum.

Owing to an omission in the first publication (1935), a misunderstanding has arisen about the number of tubes required for the test. This is how it should be carried out:

Reagents: 0.36 per cent solution of *anhydrous* sodium carbonate; 0.5 per cent solution of mercuric chloride (sublimate). Into 5 clean test tubes of 11 mm. diameter each, containing 0.2 c.c. of serum, are measured 0.1, 0.15, 0.2, 0.25, 0.3 c.c. of the sodium carbonate solution. After shaking, the same quantities of the mercuric chloride solution are added and the tubes are shaken again. Readings by daylight are taken at once and after ninety minutes:

Negative reaction: three or more tubes are *translucent. The mixture may be clear* or may show a slight opacity.

Reaction +: the first three tubes are turbid and *not translucent.*

Reaction + +: all tubes show a uniform turbidity and are *not translucent.*

Reaction + + +: a thick *precipitation* in all the tubes forms *immediately* after the addition of the reagents.

The performance of the test is extremely simple. Only the two solutions have to be prepared with absolute accuracy. If kept in the dark and at 0° C., they remain accurate for a month, after which time they have to be renewed. They should be checked from time to time by adding a drop of phenolphthalein to a mixture of equal parts of the solutions. If accurate, the mixture shows a weak pink color. It is important always to use *anhydrous* sodium carbonate.

Received for publication, April 20, 1942.

The nature of the reaction has not yet been cleared up satisfactorily. The active part of the reagent seems to be an unstable complex oxychloride of mercury, which precipitates serum protein under special quantitative, and perhaps qualitative, conditions (Ucko, 1936-1938).

The precipitate formed is serum globulin while albumin has a protective influence (Ucko, 1936). The protein concentration and the albumin-globulin ratio are, therefore, of definite importance. Other still unknown factors may play a part.

THE TAKATA REACTION

Takata's reaction, which is read after twenty-four hours, consists of a flocculation produced by addition of a strong solution of sodium carbonate, mercuric chloride, and fuchsin to a progression of serum dilutions and was designed for quite different purposes. It was Jezler who showed that this reaction is strongly positive in the sera of cirrhosis of the liver. Jezler, however, used Takata's procedure without adapting it to the new purpose. Extensive clinical studies have proved that positive Takata reactions are most frequently found in the sera of patients with liver diseases, especially with cirrhosis of the liver. Positive reactions may, however, occur in other illnesses. Multiple myelomas (Kahler's disease) always give a strongly positive reaction. Positive reactions can also be found in cases of glomerulonephritis, nephrosis, pneumonia, pulmonary tuberculosis, etc.

My procedure has the technical advantage of giving a clear end point only after ninety minutes and of allowing a gradation of the results from + to +++. A comparison of the two reactions in 132 cases by myself (1936) and of 33 cases by Guglielmini (1937) showed that the modified reaction possesses a greater certainty in indicating affections of the liver.

RESULTS OBTAINED WITH THE MODIFIED REACTION

Results are summarized in Tables I and II. The total number of cases is approximately 2,600, 373 of these being patients with liver or gall bladder lesions.

All but one of 92 cases of *Laënnec's atrophic cirrhosis* (Table I, *a*) had positive reactions (99 per cent). The reaction was +++ in 83 patients (90.2 per cent), ++ in 7, and + in one patient. Two of Cozzutti's cases had ++ reactions at an early stage. Statistics of the original Takata reaction (Schindel and Barth, 1934) have furnished only 83 per cent of positive and 6.8 per cent of doubtful (Jezler, 1938) results in liver cirrhosis.

Four cases of group *b* (Table I) had negative reactions: one with the diagnosis of chronic hepatitis (out of 4), one termed hypertrophic cirrhosis with splenomegaly (Takata's reaction negative), one hepatomegaly (Vaquez), and one hydatid cyst of the liver.

Fifteen of the 46 patients had +++ reactions. These consist of one patient with hypertrophic cirrhosis, one with amyloid degeneration of the liver, one with acute liver necrosis, 4 (of 16) with syphilitic hepatitis, one with arsenical hepatitis, one with liver abscess, one with multiple cysts of the liver, and 5 (of 7) with kala-azar. Regarding kala-azar, the formol test (gelatinization of the serum on addition of formol) may be remembered. It is due to a marked relative increase of the serum globulins (reduction of albumin?), a characteristic feature of kala-azar. Kala-azar has been included in this

group because the disturbed equilibrium of the serum proteins is probably due to the severe liver damage as a result of the protozoal infection.

One *reticulo-endothelioma* and 2 cases of *primary cancer* of the liver gave +, ++, and +++ reactions, respectively (Table I, *c*). The patient with a +++ reaction showed diffuse cirrhotic liver changes at autopsy.

*These results deviate from findings of majority of authors. See text.

Among 33 cases of *secondary carcinoma* of the liver of different origin (Table I, *d*), there were 9 negative and 4 +++ reactions. Twenty patients had + and ++ reactions. This gives a total of 24 positive reactions (73 per cent), while in a similar group of 85 cases only 30 per cent of positive Takata reactions were observed (Schindel and Barth, 1934).

All authors agree that the degree of positivity of the reaction in patients with *liver congestion* due to heart failure corresponds with the clinical condition (Table I, *e*). Only 7 of 56 cases gave negative reactions (12.5 per cent). In comparison, 44 of 45 patients with a failing heart without clinical signs of liver congestion had negative reactions (Cozzutti, Guglielmini).

The next group (Table I, *f*) contains 103 patients, mainly with lesions of *gall bladder* and *bile ducts*. Fifty-four negative reactions were found. In 3 cases with gall bladder trouble and + reactions (Cozzutti) the liver was tender and enlarged and jaundice was present. Among the 4 cases labeled "liver disorder?" only the 3 patients with positive reactions showed signs of a lesion of the liver on examination.

Sacchetti's cases with 12 ++ and 2 +++ reactions will be discussed later.

The results obtained in cases of *simple* (catarrhal) *jaundice* (Table I, *g*) are important since most patients (34 of 40) had negative reactions. Very divergent results have been obtained with Takata's reaction in cases of jaundice. Six of my own cases had positive Takata and negative modified reactions. In some cases of jaundice positive results were the first signs of more severe liver damage (Ucko, 1936). No clinical details are available about the 6 positive cases in this group.

Di Benedetto, without quoting exact figures, states that most of his patients with simple jaundice had negative reactions, some, however, + and ++ reactions. His observations have not been included in Table I.

Table II

Number		Classification	–	+	++	+++	
1.	230	Liver diseases and diseases with definite liver damage (Table I, *a-e*)	21 (9.1%)	49	51	104	=45%
				$\underbrace{\quad}_{5}$ =90.9%			
2.	143	Diseases of the biliary system, uncertain liver cases, and simple jaundice (Table I, *f, g*)	88 (61.5%)	37	16	2	=1.4%
				=38.5%			
3.	2,031 (approx.)	Other diseases	1,752 (Approx. 86.3%)	128	111	40	=2%
				=13.7%			

Taken all together, 90.9 per cent of the cases with liver affections had positive reactions while only 38.5 per cent of positive results were obtained in patients suffering from diseases related to the biliary system and from simple jaundice. The number of +++ reactions in the first group was 104 compared with only 2 in the second group (45 per cent against 1.4 per cent). Also the percentage of ++ reactions is higher in group 1 than in group 2 (23 per cent against 11 per cent) (see Table II).

Patients suffering from all common internal and neurological illnesses, as well as a number of healthy people, have been examined by the different authors in order to find out how far positive reactions are related to affections of the liver. The total number of cases (2,031) is only approximate, since many authors do not quote the exact number of their patients.

Table III gives a list of nonhepatic diseases in which positive results have been obtained. They do not occur regularly. Many patients suffering from the same illnesses have negative reactions. The number of diseases is limited, and they are on the whole those in which the original Takata reaction has also been found to give positive results.

Of the patients examined 86.3 per cent had negative reactions, 11.7 per cent + and ++ reactions, and only 2 per cent +++ reactions. The majority of

patients with ++ and +++ reactions consisted of 104 cases of malaria observed by Vesce and of 25 skin diseases observed by Bronzini. The remaining cases are 17 with ++ and only 5 with +++ reactions; 3 patients with Kahler's disease (multiple myelomas), one with diabetes and one with miliary tuberculosis, all observed by Jezler and his collaborator, Bots. None of the other authors have found +++ reactions among their nonhepatic cases. The majority of these patients had + reactions (6.3 per cent).

TABLE III

NONHEPATIC DISEASES WITH POSITIVE REACTIONS

DEGREE OF REACTION +	++	+++
Nephritis, nephrosis	Nephritis, polyarthritis	Multiple myeloma (Jezler)
Diabetes	Rheumatoid arthritis	
Pernicious anemia	Diabetes	Diabetes (Jezler, Bots)
Peliosis rheumatica	Pernicious anemia	
Carcinosis, carcinoma of pancreas	Lymphogranuloma inguinalis	
Malignant lymphadenoma	Tuberculosis of lungs, miliary tuberculosis	Tuberculosis of lung (Rubino)
Tuberculosis of lungs, pleurisy	Lung abscess, bronchiectasis	Miliary tuberculosis (Jezler)
Pneumonia, lung abscess		
Typhoid, amoebiasis, brucellosis		
Malaria	Malaria, spinal tumor, tabes, general paralysis of the insane	Malaria (Vesce)
Cerebrospinal syphilis, hemiplegia	Tuberculosis of skin, other skin diseases	Skin diseases (Bronzini)
General paralysis of the insane (G.P.I.)		

DISCUSSION

The experiences of four authors could not be included in this general survey. An article by Montalbano (1938) on the subject was unobtainable. According to Vesce (1939), this author has examined 167 patients and has found positive results in most of his liver cases. He has, however, observed +++ reactions in patients without clinical signs of liver disease.

Backert's results (1938) have been omitted because he found only one negative reaction among 125 patients with different illnesses and 10 healthy persons. This fact can only be explained by an error in his technique. Backert himself is satisfied with his results, especially with regard to liver disease.

Ornstein (1937) has not recorded the degree of positivity of the reaction. Apart from the diseases in Table III, he has encountered positive results in cases with the diagnosis of pellagra, Grave's disease, and ovarian deficiency.

Rubino's (1938) readings of the reaction differ from those put forward by those mentioned and in previous papers. His results have, therefore, not been included in Table II and are dealt with separately.

Most authors come to the conclusion that the test is a very valuable, simple, and rapid laboratory method, generally indicating hepatic involvement and thus aiding clinical diagnosis.

Cozzutti emphasized that +++ reactions may occur in cases of syphilitic hepatitis and are not specific for liver cirrhosis. Table I shows other liver affections with +++ reactions.

Guglielmini regards the new reaction as being superior to the original one and believes that reaction +++ indicates cirrhotic changes; reaction ++, local-

ized liver affections; and reaction +, simple liver congestion. This classification is not confirmed by the result of the other authors.

Sacchetti followed up cases with chronic affections of the biliary system. His number of strongly positive reactions (++ and +++) is very high. According to him, the test is of great value in indicating possible damage of the liver parenchyma. Except in an emergency, patients with gallstones should not be operated on if their serum reaction is stronger than +. In such cases medical treatment should be given first. This may lead to an improvement of the test and to better chances if surgical interference is necessary. Two of Sacchetti's cases with +++ reactions died soon after operation. The postoperative recovery of cases with ++ reactions was unsatisfactory. After successful operations the reaction became negative.

Jezler, who introduced the Takata reaction into the clinic as a liver function test, and his assistant, Bots, are not in favor of modifications of the original technique. Bots' and Jezler's liver cases are identical and have, therefore, not been included separately in Table I. Jezler's results have been marked with an asterisk to show that they generally deviate from the findings of the majority of authors (– and + reactions in liver cirrhosis, +++ reaction in liver congestion, and ++ reaction in cholangitis). He also found +++ reactions in one patient with diabetes and one with miliary tuberculosis. With regard to the negative reaction in one patient with liver cirrhosis among 92 (Table I), it is interesting to note that a series of 25 Takata-negative cases, verified at autopsy, includes 2 cases of liver cirrhosis (Jezler, 1938, p. 431).

Although positive results with the test described are not confined to liver diseases, the great number of cases collected by at least 14 different authors show clearly the enormous incidence of positive reactions when the liver is primarily or secondarily involved in the morbid condition. Positive results in nonhepatic cases are comparatively rare. There is, however, no doubt that the reaction, like the original Takata reaction, can be positive in cases without clinical or pathologic manifestations of liver disease. The test is, therefore, not a specific indication of liver disease. It can only be used as such in connection with the clinical findings. It indicates an alteration of the serum proteins of a nature which is not properly understood, but it is possible to conclude that the liver must play an important part in the etiology of this alteration. If used with the necessary precaution and in connection with the clinical observation, and if certain other causes and diseases (Table III) have been excluded, the test is undoubtedly an easy method of great value for diagnosis, prognosis, and treatment of liver disorders, and for the differential diagnosis of doubtful cases. On the strength of the observations collected in this paper it seems justified to recommend the reaction for the routine examination of possible liver affections and as a test for the liver function with regard to protein metabolism. Reactions +++ suggest the presence of a severe parenchymatous lesion or destruction of the liver. In the majority of cases this lesion is cirrhotic in nature. Other severe liver lesions of an extensive but not always diffuse character can also give +++ reactions. Marked impairment of the protein-regulating function of the liver, recognizable by a positive serum reaction, may, however, occur without gross morphologic lesion. Even a strongly positive reaction is reversible and can be affected by treatment, as in the case

of syphilitic hepatitis and liver congestion. The test is also of assistance for the differential diagnosis of jaundice since the majority of cases of simple jaundice give negative reactions. Cases of jaundice with ++ or +++ reactions should be diagnosed with caution. All my own cases with such reactions turned out not to be simple jaundice. The differential diagnosis between simple jaundice and mild hepatic necrosis, often impossible for the clinician, seems also to be facilitated by the test (see also Ucko, 1938).

TABLE IV

NUMBER	DIAGNOSIS	RESULTS	EFFECT OF TREATMENT
21	Acute and generalized exudative eczema	+++ 10 cases	Cured
10	Eczema rubrum madidans	++ 9 cases	Improved
5	Papulous eczema	+ 2 cases	Not improved
39	Different chronic eczemas	+++ 3 cases	Improved
10	Hyperkeratotic eczema of palms and soles	++ 3 cases	Cured
15	Squamous eczema	+ 5 cases	Not improved
100		32	

The occurrence of positive reactions in nonhepatic diseases suggests that alterations of the serum proteins, similar to those found most regularly in liver diseases, can take place in certain other illnesses (Table III). Some of these (e.g., diabetes, pernicious anemia, typhoid, malaria, amoebiasis, brucellosis, syphilis) even affect the liver morphologically. The involvement of this organ may account for the disturbance of the protein metabolism manifesting itself in a positive serum test. Other diseases (e.g., nephritis; Kahler's disease; focal, acute, and chronic infections like rheumatoid and other forms of arthritis; pneumonia; pleurisy; lung abscess; bronchiectasis; tuberculosis; lymphogranuloma) show no such implication of the liver. A disturbed protein metabolism in Kahler's disease, in renal and certain infectious diseases is, however, known. It has not been recognized until recently that the liver plays an important role in the regulation of protein metabolism. Liver function tests (glucose, levulose, and galactose tolerance, hippuric acid formation, etc.) have shown impaired liver function in illnesses where no hepatic involvement was expected. There is strong evidence that the liver is responsible for the alteration of the serum proteins in hepatic diseases. While the matter is open to discussion, it is very likely that the liver is also responsible for the disturbance of the protein metabolism in those nonhepatic diseases where such a disturbance is a regular occurrence. The alteration of the serum proteins, which leads to a positive serum reaction, would then be the manifestation of a liver disturbance brought about by the causative agent. Apart from its practical significance the test, therefore, draws attention to the liver in diseases with disturbed protein metabolism and to the role of this organ in protein synthesis and equilibrium.*

SPECIAL INVESTIGATIONS

Some authors have used the test for determining the liver function in certain illnesses. Their results merit special consideration.

* [illegible] with the cephalin-cholesterol flocculation test (Hanger, F. W.: J. Cli[illegible] 1, 1939; Rosenberg, D. H.: Arch. Surg. 43: 231, 1941) give results almos[illegible] obtained by the modified Takata test, and it will be interesting to compare both reactions on the same cases. The similarity of the results of the two different tests in certain nonhepatic diseases points to a liver dysfunction rather than to an unspecific alteration in such cases.

1. *Malaria.* Vesee (1939) examined 137 cases of African malaria. The incidence of positive reactions was surprisingly high. He found 82 ++ and 22 +++ reactions. Provocation by injection of a concentrated liver extract and adrenalin and by violent physical exercise had no appreciable influence on the results. To explain the great number of positive results, Vesee puts forward the theory that a positive reaction indicates a functional disturbance of the reticulo-endothelial cells rather than of the liver cells, the former being permanently damaged by the malarial infection. This theory is interesting and could perhaps be further substantiated by experimental damage to the reticulo-endothelium without involving the liver cell, but the strongly positive reaction in cirrhosis of the liver with extensive destruction of the liver parenchyma and, on the other hand, a weakly positive reaction (+) found in a case of reticulo-endothelioma (Table I, *c*) does not render this conception very probable.

2. *General paralysis of the insane.* Angrisani (1937) examined the sera of 95 cases of general paralysis of the insane. Fifty-four patients had negative reactions, 3 had +, 2 had ++ reactions. No +++ reaction was found. The five patients with positive reactions all had clinical signs of liver damage, either of specific or postmalarial origin. Similar results were obtained by the author with van den Bergh's and with Bengal red test. He concludes that liver damage in general paralysis of the insane, occurs rarely and disputes the observations of Cassiano (1935), who found frequently positive results using the original Takata reaction.

3. *Pregnancy.* The majority of pregnant women examined by Zambonini (1938) had negative reactions. Among 120 cases of normal pregnancy only 11 (9 per cent) had a + reaction. No ++ or +++ reactions were found. Reactions + occurred most frequently during the third and sixth months of pregnancy. There was no difference between primiparas and multiparas. Unfortunately, no examinations were made in cases of pathologic pregnancy or toxemia.

4. *Skin diseases* (Eczema). Bronzini (1938) studied the reaction in 100 cases of different eczematous conditions. The number of strongly positive reactions is unusually high and throws doubts on his experimental technique. Patients with positive tests were also treated for possible liver damage, but the author does not state anything about the nature of this treatment. His results are included in Table II and are in detail in Table IV. If they can be confirmed by others, they would represent an important contribution to our conception of eczematous conditions.

5. *Lung tuberculosis.* Rubino (1938), who examined 200 cases of pulmonary tuberculosis, compared the results of the test in 36 patients with the amino acid curve in the blood after ingestion of glycine, a procedure which is used as a liver function test. The author does not give exact figures. He states that 30 per cent of his cases had negative reactions, 30 per cent had + and ++ reactions, and 40 per cent had +++ reactions. The latter include "immediate and delayed +++ reactions," but since only an immediate precipitation can be regarded as a +++ reaction, Rubino's classification of results may be ignored. Positive reactions in cases of lung tuberculosis have been found by other authors but never in such a high percentage of cases. Rubino states that the degree of positivity in his series corresponded with the severity of the tuberculous lesion. He, therefore, regards the test as a useful addition to other

methods for diagnosing the degree of activity of the tuberculous process. He noted that the result of this test and tests of the blood sedimentation rate were usually parallel. This fact has not been observed by other authors. He found, however, positive reactions with a normal sedimentation rate. The glycine reaction showed disturbed liver function in an unspecified number of cases, but the author's reaction corresponded with the glycine test in only 50 per cent of the cases. Rubino concludes that the reaction furnishes no indication of a liver deficiency: he disregards the fact that both tests measure different types of liver function. The importance of his observations lies in the close relationship he found between positive reactions and the severity of the tuberculous lesion and in the demonstration of a damaged liver function in cases of lung tuberculosis. Disturbances of protein metabolism in cases of severe tuberculosis have been demonstrated earlier; the albumin fraction of the serum is generally diminished; the globulin fraction, and especially fibrinogen, is increased. This may well be due to damage to the liver and impairment of its regulation of protein metabolism.

THE CEREBROSPINAL FLUID

Takata and Ara (1936) applied the original test to the cerebrospinal fluid and found it to be positive mainly in cases of syphilis of the nervous system. The Takata reaction has, however, not become a routine test for the examination of the cerebrospinal fluid because it had no advantages in comparison with other protein reactions and the results were not found to be specific for syphilis.

Three authors studied the new modification of the test on the cerebrospinal fluid. Zanetti's paper (1938) "Neurosyphilis and Ucko Reaction" was not obtainable in this country.

Ornstein (1937) examined the cerebrospinal fluid of 46 cases of general paralysis of the insane, and of 12 cases of tabes and compared the results with those of the Wassermann and Meinicke tests. The cerebrospinal fluid of 22 patients with negative Wassermann and Meinicke reactions were tested in comparison. His results are summarized as follows:

NUMBER	DIAGNOSIS	WASSERMANN		MEINICKE		UCKO	
		+	–	+	–	+	–
46	General paralysis of the insane	46	–	46	–	46	–
12	Tabes	8	4	8	4	8	4
22	Other affections	–	22	–	22	–	22

These data show a complete correspondence of the three reactions, and Ornstein concludes that the test is more valuable than Meinicke's and other reactions owing to its simple technique.

A very important contribution was made by Fleischhacker (1938). This author used only one tube, adding the lowest concentration, i.e., 0.1 c.c. of each reagent to 1.0 c.c. of cerebrospinal fluid. If the cerebrospinal fluid is free from blood and is not contaminated by bacteria, a positive reaction (marked opacity or precipitation) appears between forty-five and ninety minutes. Fleischhacker examined 153 cases of treated and nontreated general paralysis of the

insane and 24 different nervous and mental disorders and compared the results with the reactions of Weichbrodt, Pandy, Lange, and Wassermann.

In 61 cases of general paralysis of the insane all the reactions were positive. In 92 treated cases the results were as follows:

UCKO		LANGE AND PANDY		WASSERMANN		SERUM—WASSERMANN	
+	−	+	−	+	−	+	−
36	36	0	92	10	82	31	61

Twenty-four nonsyphilitic cases gave the following reactions:

DIAGNOSIS	UCKO		LANGE		PANDY	
	+	−	+	−	+	−
Cerebral tumor	2	−	−	2	−	2
Cerebral thrombosis	1	−	−	1	−	1
Disseminated sclerosis	1	−	−	1	−	1
Mental deficiency	3	3	−	6	−	6
Organic disorder?	7	4	−	11	2	9
Angioma cerebri	−	1	−	1	−	1
Posttraumatic psychosis	−	1	−	1	−	1
Fracture of skull	−	1	−	1	−	1

It can be concluded from the results that the reaction is not specific for syphilis but indicates generally abnormal protein conditions in the cerebrospinal fluid. Without being hypersensitive the test is more sensitive and, therefore, superior to Pandy's protein reaction usually made in the routine examination of the cerebrospinal fluid. The reaction may still be obtained—as in the case of treated general paralysis of the insane—when all other findings are apparently negative. It would be of interest to test cases of mental disorders, since Fleischhacker found positive reactions in cases of mental deficiency indicating lesions not detectable with the usual methods.

SUMMARY

The experience of different authors on approximately 2,500 cases with a simple and rapid modification of the Takata reaction is summarized and discussed.

Ninety per cent of patients suffering from liver diseases had positive reactions while at least 86 per cent of negative reactions were encountered in patients suffering from other illnesses. The test which indicates an alteration of the serum proteins seems to measure the liver function with regard to protein metabolism. Certain nonhepatic diseases frequently, but not always, give positive reactions. The problem of whether a positive test in these illnesses means a disturbance of the protein-regulating function of the liver or whether it occurs independently is discussed.

The experience of a number of authors with the test in cases of general paralysis of the insane, pregnancy, skin diseases, and tuberculosis is given in detail.

The reaction, which has also been applied to the cerebrospinal fluid, seems to be more sensitive than the routine tests for protein. It will, therefore, be of value in detecting minor alterations of the cerebrospinal fluid in disorders of the nervous system.

THE EFFECT OF ASCORBIC ACID (VITAMIN C) ON THE SENSITIVITY TO SALICYLATES IN A CASE OF RHEUMATIC FEVER

Louis Pelner, M.D., Brooklyn, N. Y.

A SEVERE case of rheumatic fever that rapidly became intolerant to salicylates was observed recently. The intolerance was manifested by a marked ringing in the ears that continued in spite of the reduction of the drug to a very low and ineffective amount. At about the same time, the occurrence of several severe nosebleeds, as well as a positive tourniquet test, and a low plasma ascorbic acid content, suggested the use of large amounts of ascorbic acid. The previous diet was analyzed and was found to be markedly deficient in vitamin C. Dramatically enough, the nosebleeds and the severe tinnitus ceased after forty-eight hours of vitamin C therapy and did not return, although the salicylates were increased to the initial high level and were continued in this manner for ten additional days.

Some observers[1] have pointed to a deficiency of vitamin C in acute rheumatic fever. This deficiency may predispose the person to toxic reactions to certain drugs, e.g., in this case salicylates. In any event, the toxic reaction ceased when vitamin C was given in adequate amounts.

CASE REPORT

P. V., a 15-year-old male, suddenly developed a high fever (104° F.); rapid pulse rate (130), pain in both shoulders, and dyspnea. The boy had no history of any previous serious disease and was in excellent health until the onset of the present illness. The mother is a rheumatic cardiac with both mitral and aortic murmurs, and a recent history of an attack of myocardial failure.

Examination of the patient revealed a rough, to-and-fro leather-like murmur over the base and apex of the cardiac area. There were no signs in the lungs or elsewhere. There was no swelling, redness, or limitation of motion in the shoulder joints, or in any other joints of the body. The pain in the shoulder joints was apparently due to a reflex mechanism. The to-and-fro pericardial friction rub was evanescent, lasting only a few hours. The sedimentation time was extremely rapid, twenty minutes for an 18 mm. fall. The blood count was white blood cells 15,200, polymorphonuclear leucocytes 85 per cent, lymphocytes 12 per cent, monocytes 3 per cent, hemoglobin 85 per cent, red blood cells 4,350,000. A diagnosis was made of rheumatic carditis.

Sodium salicylate was started at the rate of 15 grains (1 Gm.) every four hours combined with 5 grains (0.3 Gm.) of sodium bicarbonate. In addition, 60 grains (4 Gm.) of sodium salicylate was given by rectum once a day. On the third day of illness and salicylate medication, the patient developed a nosebleed and severe ringing of the ears. During the next two days the tinnitus continued severely in spite of the reduction of salicylate medication to 15 grains a day by mouth. The nose bled profusely during this time. A tourniquet test showed twelve petechiae in a 2.5 cm. circle after fifteen minutes of positive pressure. The plasma ascorbic acid content was 0.4 mg. per 100 c.c. (Farmer and Abt[2] method—normal value equals 0.7 mg. per 100 c.c.) It was, therefore, decided to give the patient large amounts of vitamin C. In addition, the diet of this patient over the preceding four weeks was reviewed and was found to be markedly lacking in foods containing vitamin C.

One hundred milligrams of ascorbic acid were given by mouth three times a day. Within forty-eight hours the nosebleed, as well as the ringing in the ears, had ceased. The salicylates were then stepped up to the former doses without development of tinnitus, or indeed

Received for publication, April 23, 1942.

any other sign of intolerance. The combined medication was continued for ten days without any ill effect. Urine examination was entirely negative for signs of renal irritation. The patient made an uneventful recovery, with a residual mitral systolic murmur as a sequel.

COMMENT

There is some evidence to show that in the guinea pig, chronic scurvy with a superimposed infection of β-streptococci produces lesions similar to those found in acute rheumatic fever.[1, 3] Scurvy alone does not produce the characteristic lesion. Clinically also, the ascorbic acid level of the blood plasma was found to be low in a group of patients[1] with rheumatic fever. It can easily be shown that rheumatic fever is a disease of the poor and undernourished,[4] and also that latent scurvy and rheumatic fever occur late in winter and early in spring, during the very same period that vitamin C is less widely available in foods.[5] However, the treatment of rheumatic fever patients with vitamin C in adequate amounts has proved disappointing.[6] Perla and Marmorston[7] believe that this does not rule out the connection between vitamin C and rheumatic fever, for vitamin C deficiency might enable the streptococcus to gain a foothold in these patients. Once this has been attained, vitamin C itself cannot affect the pathologic picture or prevent a recurrence. These authors feel that there exists some relationship between the lower vitamin C content of the blood and rheumatic fever, even though the connection has not been incontrovertibly proved as yet.

There also appears to be much evidence that an excess of vitamin C is a prophylactic against the toxic effects of neoarsphenamine and some other drugs. Vitamin C has been used with success in the control of reactions of certain patients to neoarsphenamine. In these persons, there may have been an insufficiency of the vitamin in the diet, and its value may be due to this fact. Recently, Marin[9] observed cases of mercurial and bismuth stomatitis among syphilitic patients, and administered ascorbic acid since it was decreased in the blood and urine. The ascorbic acid cured ten cases of this complication.

In this study the presence of a large amount of vitamin C in a patient who had a low serum ascorbic acid level, and other evidences of vitamin C deficiency appeared to remove the evidence of salicylate toxicity (marked tinnitus). At the same time marked nasal hemorrhages ceased wtihout recourse to packing or cauterization. It is suggested by one author that the hemorrhagic manifestations of rheumatic fever are due to a vitamin C deficiency.[1] In the study of bismuth and mercury sensitivity cited,[9] the author stated that vitamin C was necessary for the metabolism of these substances in the body; if it was not present in sufficient amounts toxicity would supervene. This may also be true in the case of salicylate sensitivity. This is suggested by the following simple experiment:

EXPERIMENT

To a test tube containing 5 drops of 1 per cent methylene blue solution in 5 c.c. of water a few crystals of ascorbic acid are added. On heating the tube the blue solution is immediately decolorized and a white solution results. The methylene blue is apparently reduced by the ascorbic acid. To another test tube containing 5 drops of 1 per cent methylene blue solution in 5 c.c. of

water, some sodium salicylate crystals are added, and the resulting mixture is allowed to stand. Even though vitamin C is later added in large amounts, as high as 50 to 100 mg., and the resulting solution is heated, no decolorization results. The vitamin C has apparently been fixed by the sodium salicylate and the methylene blue is not reduced.

It is possible that in the body sodium salicylate has an affinity for ascorbic acid and binds it, so that less and less is available for other functions. However, this conclusion cannot be drawn from the foregoing simple experiment.

Whatever the relationship of the lack of ascorbic acid to the toxicity of sodium salicylate, it would seem to be worth while to study the problem further, to see whether it is widely applicable. Certainly it can be said that in this case, saturation of this patient with large amounts of vitamin C (normal daily requirement is approximately 50 mg.)[10] enabled the continuation of salicylate medication and appeared to have a salutory affect on the nosebleed.

CONCLUSIONS

1. A severe case of rheumatic carditis became intolerant to sodium salicylate early in the course of the illness.
2. A low plasma ascorbic acid content, positive tourniquet test, and severe nosebleed suggested the presence of vitamin C deficiency.
3. The preceding diet of this patient proved to be deficient in vitamin C.
4. After the vitamin C intake was increased, sodium salicylate was again given in large amounts with impunity.

EFFECT OF TRASENTIN A, TRASENTIN, AND MORPHINE ON RESPIRATION*

N. TOBOLOWSKY, M.D., DONALD SLAUGHTER, M.D., T. U. JOHNSON, M.D. AND R. E. VAN DUZEN, M.D., DALLAS, TEXAS

IT HAS been shown that trasentin is antagonistic to the actions of morphine on the bladder,[1] and recent experimental evidence has furnished confirmation of such action in regard to trasentin A on the isolated ureter.[2]

As it is possible that trasentin and its chemical allies are capable of inhibiting certain morphine effects other than on the bladder and ureter, it seemed of interest to investigate the relationship of effects on respiration using trasentin, trasentin A, and morphine in various combinations. Morphine and trasentin are both used therapeutically in certain combinations, such as ureteral colic.

PROCEDURE

In this work, 58 experiments were performed on dogs and 21 on cats. Respiration was recorded by means of a blunt intrapleural trocar connected to a sensitive tambour. The details of this simple, but very satisfactory, device are shown in Diagram 1. This apparatus may be used on unanesthetized as well as on anesthetized animals. When used in the former instance, a small amount of 1 per cent procaine hydrochloride is injected beneath the skin between the fifth and sixth interspace in the midaxillary line. A very small incision is then made through the skin with a scalpel, and the trocar is pushed with a craniad motion gently, but firmly, through the intercostal muscles and parietal pleura into the pleural cavity. It is very easy to accomplish this procedure without puncturing the lung, since the trocar falls into the space between the parietal and visceral pleura when resistance of the parietal pleura is overcome. Immediately upon entering the pleural cavity, respiratory excursions are recorded, provided no air has entered the cavity during the introduction of the trocar. To insure the prevention of pneumothorax, suction is applied to the T-tube after insertion and before withdrawal of the trocar. If air entered during the insertion of the apparatus and is removed by suction, it takes about three to four minutes for equilibrium to become established. We feel that this method is an excellent one to record direct respiratory movements, since there are no

*From the Department of Physiology and Pharmacology, Baylor University College of Medicine, Dallas.

Trasentin A is phenylcyclohexyl acetic acid ester and is available only for experimental use. It is now designated as trasentin 6-H.

Trasentin is diphenylacetic acid diethylaminoethanol ester.

Grant in aid to one of us (D.S.) given by Ciba Company, Summit, N. J., who also kindly furnished the trasentin A and trasentin used in this study.
Received for publication, April 24, 1942.

by-passes or hindrances and there is no lag in the recording of all respiratory waves. This method also has the advantage of being used many times for the same animal, thus making each animal his own control.

We at first tried without success to slow respiration with large doses of morphine given subcutaneously or intravenously in unanesthetized dogs. Finally, we made use of a standard technique of anesthetizing the dog with 26.1 mg. per kilogram of pentobarbital. As soon as the anesthesia was complete, the animal was placed on the table and the trocar was inserted and connected to the tambour. After suitable control respiratory records were made, 5 mg. per kilogram of morphine were injected intravenously. This method gave uniform slowing of respiration.

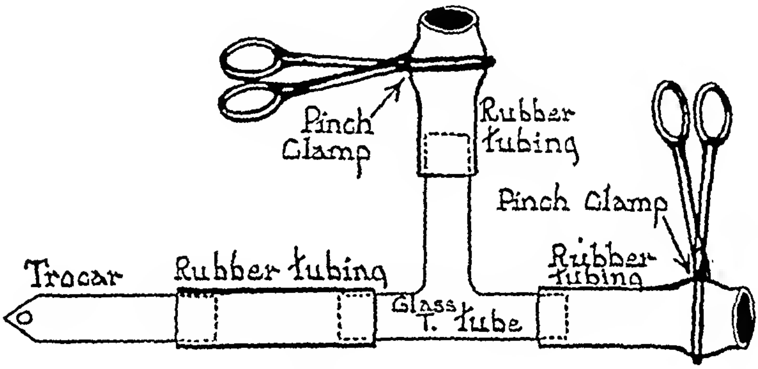

Diagram 1.—A schematic representation of the intrapleural trocar used in the experiments to record respiration.

In a certain number of acute experiments blood pressure and respiration were recorded simultaneously. Anesthesia was induced by pentobarbital, or barbital urethane administered intraperitoneally. All the cats and a few dogs used in this study were so treated.

As a rule, 6 mg. per kilogram of trasentin and 2 mg. per kilogram of trasentin A were given intravenously.

A few experiments were done on blood pressure alone, and the effects of trasentin A with and without intact vagi were compared.

RESULTS

In general, the results indicate that trasentin and trasentin A prevent depression of respiration by morphine when they are given before, after, or with morphine. When the trasentins are given with morphine, they never add to the depression of respiration produced by this opiate.

Fig. 1 illustrates well the effects of trasentin A and morphine on respiration of the dog. As noted on the tracings, these animals received pentobarbital previously.

Fig. 1A shows that 5 mg. per kilogram of morphine were given intravenously and (usually almost at once) marked depression of respiration ensued

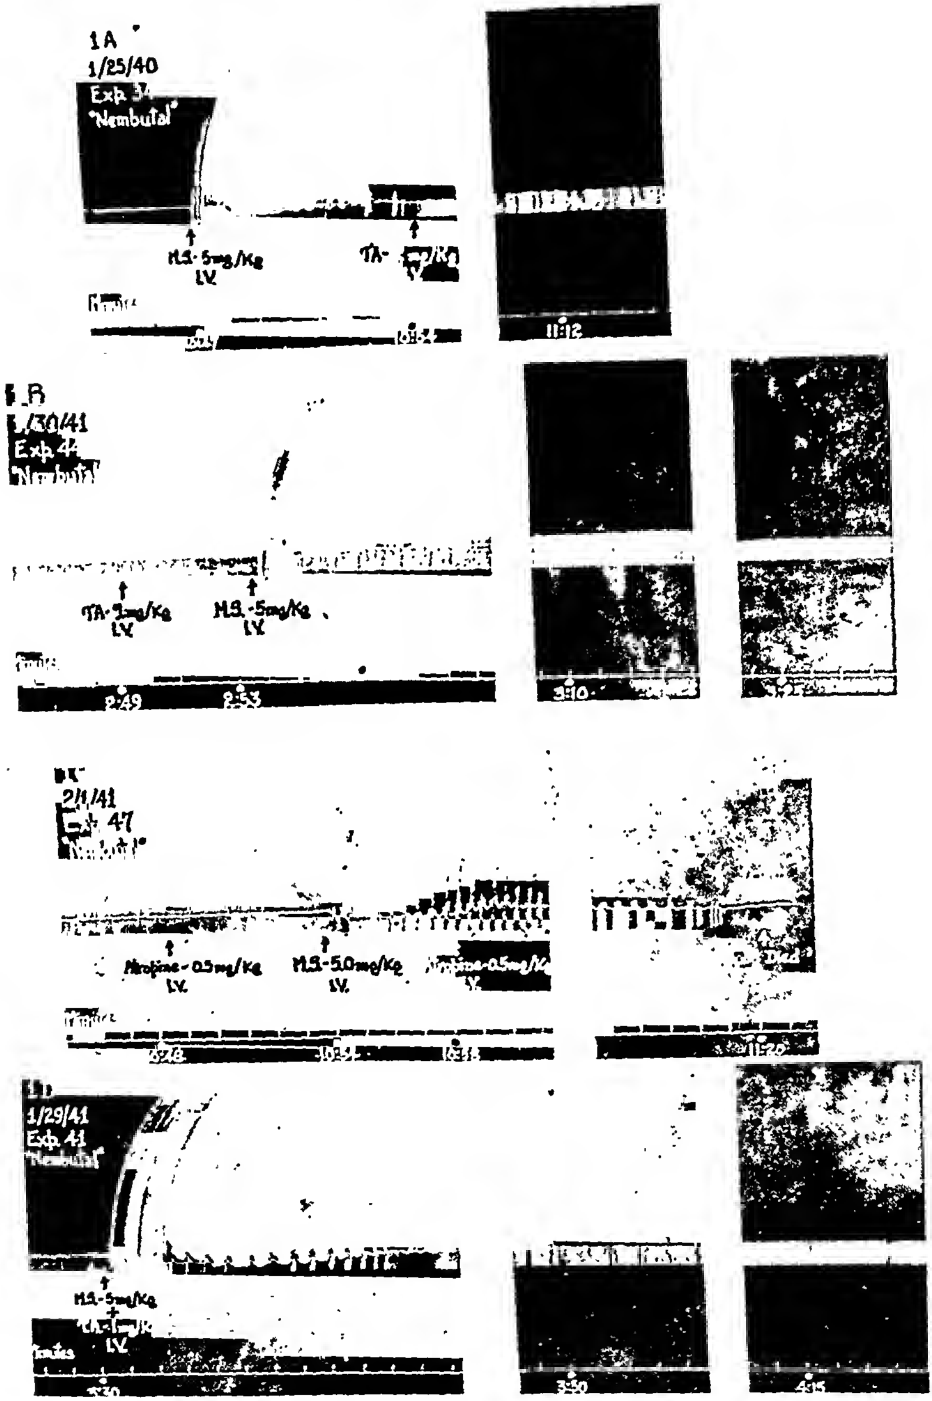

Fig. 1.—*A*, This tracing exhibits the effectiveness of trasentin A to counteract the depressant effect of morphine on respiration. Both drugs were given intravenously. Time trace, minutes. Kymograph speed, 15 mm. per minute. M.S. = morphine sulfate. T.A. = trasentin A.

B, This tracing illustrates the ability of trasentin A to prevent the depressant effects on respiration by morphine. Both drugs were given intravenously.

C, This tracing illustrates the failure of atropine not only to prevent but also failure to correct depression of respiration by morphine. Both drugs were given intravenously. Time trace, minutes. Kymograph speed, 15 mm. per minute. M.S. = morphine sulfate.

D, This tracing presents evidence that when morphine and trasentin A are given together the depressant effects of morphine on respiration are reduced. This was a smaller dose of trasentin A than that usually employed. Both drugs were given intravenously.

Note that in tracings shown in Fig. 1*A*-*D* there was at first a brief but sharp increase in respiration when morphine was administered.

following the brief stimulation. (This latter effect will be commented on in the discussion.) When 2 mg. per kilogram of trasentin A by intravenous injection were then given eight minutes later, the respiration returned to an amplitude and rate greater than the normal rhythm preceding the injection of morphine.

Fig. 1*B* shows that 2 mg. per kilogram of trasentin A administered intravenously four minutes before 5 mg. per kilogram of morphine entirely prevented depression of respiration by morphine. This is a very important finding since a large percentage of animals died after receiving such a dose of morphine alone. When one compares this preventative and corrective action of trasentin A with that of atropine, the difference is very striking. Fig. 1*C* demonstrates not only the failure of atropine in a dose of 0.5 mg. per kilogram intravenously to prevent the depressant effect of morphine on respiration, but also its failure to correct the depressant effect of this hypnotic as well. As a consequence, the animal died from the effects of the morphine. This was the usual finding in these experiments.

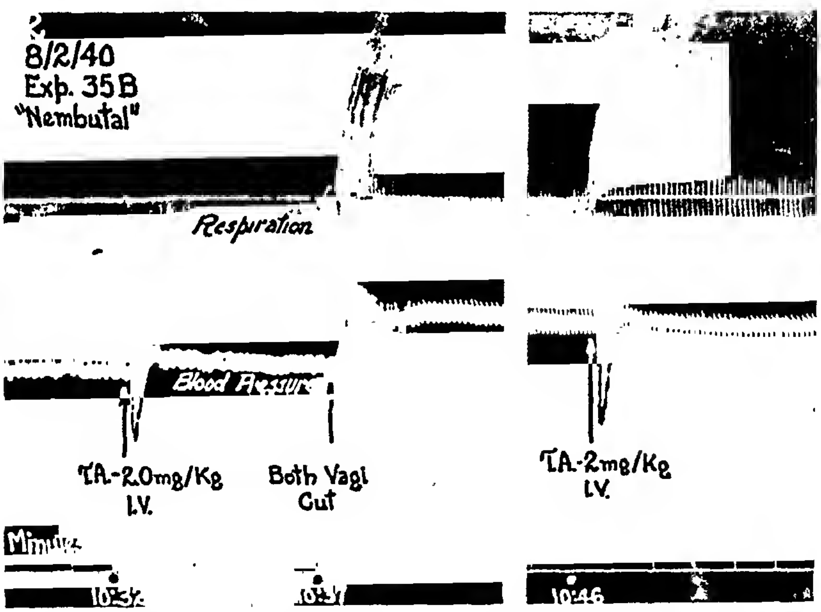

Fig. 2.—This tracing illustrates the effect of trasentin A on respiration and blood pressure. When given intravenously by itself, note the increased amplitude of respiration. The fall in blood pressure resembles that of acetylcholine and is present whether the vagi are present or divided. Time trace, minutes. Kymograph speed, 15 mm. per minute. M.S. = morphine sulfate. T.A. = Trasentin A.

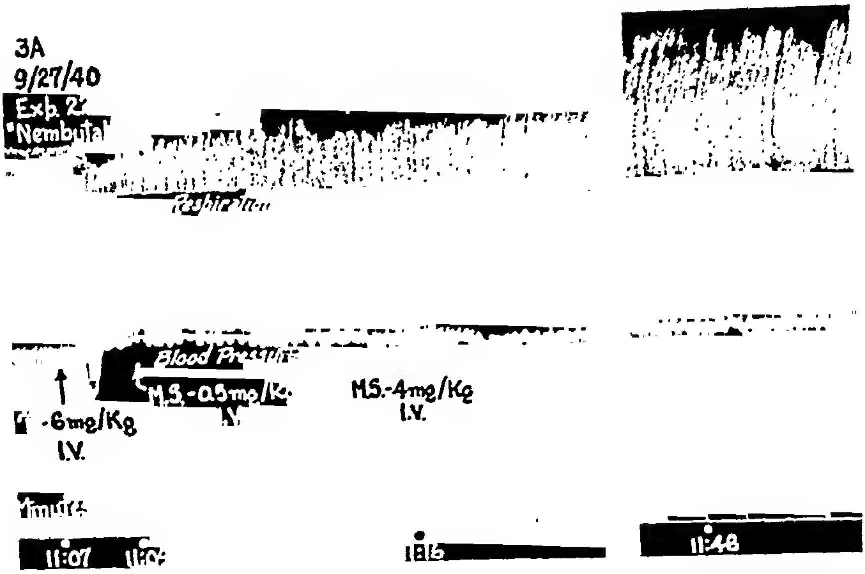
Fig. 1*D* shows a combination of 5 mg. per kilogram of morphine plus only 1 mg. per kilogram of trasentin A administered intravenously. Even with this small dose of the latter drug, the depressant effect of morphine on the respiration lasted only about nine minutes, and thereafter the respiration returned to above the normal rhythm when compared with the rate and amplitude before these drugs were given. This clearly demonstrates the protective action of trasentin A.

In other instances large subcutaneous doses of morphine alone were given and marked depression of respiration followed. Here, as already noted, trasentin A corrected the inhibitory effect of the hypnotic.



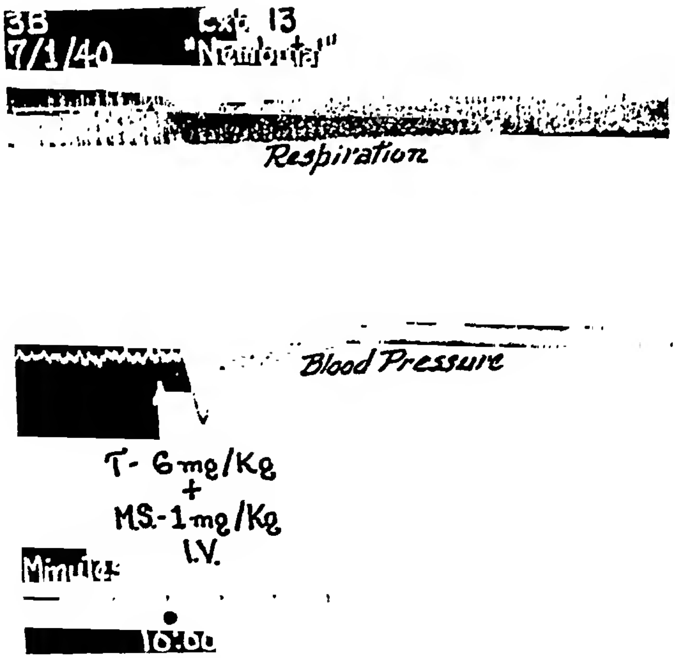


Fig. 3.—*A*, This tracing illustrates the effect of trasentin in preventing depression of respiration by morphine. Note the acetylcholine-like fall of blood pressure produced by trasentin. Both drugs were given intravenously. Time trace, minutes. Kymograph speed, 15 mm. per minute. M.S. = morphine sulfate. T. = trasentin.

B, This tracing presents the constant finding of stimulation of respiration when trasentin and morphine are administered intravenously as a single dose. Note that the blood pressure did not fall to any greater extent than when trasentin was given by itself, as seen in Fig. 3*A*.

Results similar to these were obtained in the cat, but the effectiveness of trasentin A was not as marked, since in our hands morphine alone tended to stimulate respiration. However, it has been shown that large, repeated doses of morphine will produce respiratory depression in the cat and evidence of the ability of trasentin A to prevent this depression has been obtained.

Simultaneous records of blood pressure and respiration were made under pentobarbital anesthesia (Fig. 2). In this tracing 2 mg. per kilogram of trasentin A given intravenously produced an acetylcholine-like fall in blood pressure. The vagi were then divided, and the trasentin A administration was repeated. The fall in blood pressure was still present and of the same magnitude, and it is seen that the amplitude of respiration is improved. Other experiments using doses of atropine which would paralyze the vagi before the administration of trasentin gave similar results. These results indicate that trasentin A acts beyond the vagus.

Effects with trasentin and morphine were of a slightly different nature than with trasentin A and morphine, although they pointed in the same direction. Fig. 3*A* shows the effect of 6 mg. per kilogram of intravenous trasentin on a dog that was anesthetized with pentobarbital. The blood pressure change is similar to that of trasentin A, but the fall is not as great. This is of interest, since the dose of trasentin used was three times that of trasentin A. As noted in this tracing, the respiration was stimulated and successive doses of 0.5 and 4 mg. per kilogram of morphine given intravenously failed to produce any depression. This result, however, was not as consistent as that noted with trasentin A. Fig. 3*B* illustrates the most significant and constant effect of trasentin. Here intravenous trasentin and morphine given together always produced stimulation of respiration. In this instance, only 1 mg. per kilogram of morphine plus 6 mg. per kilogram of trasentin was used, but the latter dose in combination with larger doses of morphine (up to 6 mg. per kilogram) gave a similar effect. It will be noted that the combination of morphine and trasentin, as seen in Fig. 3*B*, gives a fall in blood pressure of no greater depth than the trasentin alone, as noted in Fig. 3*A*.

DISCUSSION

These results clearly indicate that trasentin A and trasentin when administered before, after, or with morphine do not add to any depression of respiration caused by morphine. This correlates well with the previously described effects of the trasentin on the activity of the bladder[1] and the ureter.[2] Hence we feel that *experimental* evidence in animals does not indicate that it is dangerous to give these drugs to human beings with or following morphine.

Maloney and Tatum[3] have reported that morphine increases the effectiveness of inhibitory vagal impulses on respiration in the rabbit. This suggests that morphine might depress respiration at least partly by a central, cholinergic action on the vagus. The possibility that morphine possesses central cholinergic actions has been postulated.[4] This work concerned potentiation of morphine relief of pain by prostigmine. Since this potentiation occurred and since morphine acts centrally, it was suggested that morphine had a central cholinergic effect. That there is a good possibility that central cholinergic transmission occurs has been suggested by Adam and others.[5] Since the trasentins are believed to be anticholinergic in activity as well as antimyonergic on smooth muscle, they may counteract morphine depression of respiration in this fashion. It is, of course, possible that they may also stimulate the respiratory center.

When one compares the effectiveness of the trasentins on respiration depressed by morphine, trasentin A (on basis of dosage) is three times as efficient.

Simultaneous records of blood pressure and respiration were made under pentobarbital anesthesia (Fig. 2). In this tracing 2 mg. per kilogram of trasentin A given intravenously produced an acetylcholine-like fall in blood pressure. The vagi were then divided, and the trasentin A administration was repeated. The fall in blood pressure was still present and of the same magnitude, and it is seen that the amplitude of respiration is improved. Other experiments using doses of atropine which would paralyze the vagi before the administration of trasentin gave similar results. These results indicate that trasentin A acts beyond the vagus.

Effects with trasentin and morphine were of a slightly different nature than with trasentin A and morphine, although they pointed in the same direction. Fig. 3*A* shows the effect of 6 mg. per kilogram of intravenous trasentin on a dog that was anesthetized with pentobarbital. The blood pressure change is similar to that of trasentin A, but the fall is not as great. This is of interest, since the dose of trasentin used was three times that of trasentin A. As noted in this tracing, the respiration was stimulated and successive doses of 0.5 and 4 mg. per kilogram of morphine given intravenously failed to produce any depression. This result, however, was not as consistent as that noted with trasentin A. Fig. 3*B* illustrates the most significant and constant effect of trasentin. Here intravenous trasentin and morphine given together always produced stimulation of respiration. In this instance, only 1 mg. per kilogram of morphine plus 6 mg. per kilogram of trasentin was used, but the latter dose in combination with larger doses of morphine (up to 6 mg. per kilogram) gave a similar effect. It will be noted that the combination of morphine and trasentin, as seen in Fig. 3*B*, gives a fall in blood pressure of no greater depth than the trasentin alone, as noted in Fig. 3*A*.

DISCUSSION

These results clearly indicate that trasentin A and trasentin when administered before, after, or with morphine do not add to any depression of respiration caused by morphine. This correlates well with the previously described effects of the trasentin on the activity of the bladder[1] and the ureter.[2] Hence we feel that *experimental* evidence in animals does not indicate that it is dangerous to give these drugs to human beings with or following morphine.

Maloney and Tatum[3] have reported that morphine increases the effectiveness of inhibitory vagal impulses on respiration in the rabbit. This suggests that morphine might depress respiration at least partly by a central, cholinergic action on the vagus. The possibility that morphine possesses central cholinergic actions has been postulated.[4] This work concerned potentiation of morphine relief of pain by prostigmine. Since this potentiation occurred and since morphine acts centrally, it was suggested that morphine had a central cholinergic effect. That there is a good possibility that central cholinergic transmission occurs has been suggested by Adam and others.[5] Since the trasentins are believed to be anticholinergic in activity as well as antimyonergic on smooth muscle, they may counteract morphine depression of respiration in this fashion. It is, of course, possible that they may also stimulate the respiratory center.

When one compares the effectiveness of the trasentins on respiration depressed by morphine, trasentin A (on basis of dosage) is three times as efficient.

days and 0.4 c.c. for the second period of thirty days; the dogs, 1 c.c. throughout the duration of the treatment. The methylglucamine was prepared as a 6.2 per cent solution, so that each rabbit received 12.4 mg. and each dog 62 mg. of this salt per dose; the glucophylline was prepared as a 10 per cent solution (in the formula the ratio of methylglucamine to theophylline is 1:16 to 1:18), so that each rabbit received approximately 10 mg. for thirty days and 20 mg. later, and each dog received approximately 50 mg. of each of the two constituents in the compound. On the basis of the initial weight the milligram per kilogram dose was then computed for each animal. This figure appears in the respective tables. Injections were all made intraperitoneally once daily. All the animals in the two species were kept under similar environmental conditions and were provided at all times with an excess of food and water. Weights were recorded at weekly intervals. With the exception of one control rabbit, which died on the twenty-fourth day of the experimental period, all animals lived to the end and without exception appeared to maintain normal health throughout. The dogs in the glucophylline group (No. 3) were definitely more

TABLE I

WEIGHT CHANGES IN DOGS

GROUP	ANIMAL	DOSE TOTAL	INITIAL WEIGHT (KG.)	54 DAYS FINAL WEIGHT (KG.)	% DECREASE	WEIGHT LOSS (KG.)
Control (Saline)	1	1 c.c.	8.3	7.7	7	0.6
	2	1 c.c.	11.4	10.9	4	0.5
	3	1 c.c.	11.1	10.1	9	1.0
Methylglucamine hydrochloride	4	6 mg./kg.	10.3	10.2	1	0.1
	5	6.7 mg./kg.	9.2	8.0	13	1.2
	6	5.4 mg./kg.	11.5	9.9	14	1.6
Glucophylline	7	10.8 mg./kg.	9.2	6.93	25	2.3
	8	10.1 mg./kg.	9.9	9.6	3	0.3
	9	10.3 mg./kg.	9.8	9.1	7	0.7

active and lively than the others. It is of interest to note that the animal caretaker, who had no knowledge of what the animals being injected were receiving, volunteered the observation that the group of rabbits which we were treating with glucophylline ate more food and drank more water than those making up the other group; and that the amount of feces and urine voided by these animals was considerably greater. Reference to Table II reveals a fairly uniform average percentage of weight gains for the several groups both from the initial doses and after the doses were doubled. In the first series the order of percentage increases for the thirty-day period was: no medication, 47; physiologic saline, 59; methylglucamine, 49.5; glucophylline, 49. By the end of the first thirty days, then, the animals in all groups had made substantial weight gains, some of them better than 50 per cent. This, no doubt, accounts for the gradual tapering off of weight increases during the second phase of the experiment when the doses were doubled. Most of the animals had already reached maturity, after which weight increase was due primarily to deposition of fat and only secondarily to actual body growth. The total group average percentage gains were: no medication, 136; saline, 150; methylglucamine, 139; and glucophylline, 128.

FURTHER STUDIES ON GLUCOPHYLLINE*

A. H. Maloney, Ph.D., M.D., Washington, D. C.

IN A PREVIOUS report on the diuretic activity of glucophylline by Maloney, Burton, and Robinson,[1] in which experimental data were presented regarding the action of this double salt of theophylline and methylglucamine, a xanthine compound exhibiting the very desirable properties of high diuretic efficiency with long duration of action, it was indicated that our study was being continued with the object of determining "whether glucophylline exerts any untoward effects on the liver or kidney." The present report sets forth these and other pertinent results obtained from this investigation. The study was conducted in three parts, viz., the effect on (1) weight, (2) blood, and (3) vital organs. Full-grown dogs and immature rabbits were employed.

1. Weight. A. Dogs: Nine full-grown dogs, ranging in weight from 8.2 to 11.5 kg., were divided into groups of three and treated with physiologic saline (controls), methylglucamine, and glucophylline, respectively. All the animals lost weight during the course of the fifty-four days of the experimental period. The percentage loss in each group was 6.7, 9.3, and 11.6 in the order named. We do not think the medicaments played any significant role. The determinants here were probably the new diet and the unaccustomed artificial environment of the kennels (see Table I).

B. Rabbits: Thirty-six female rabbits, ranging in weight from 0.8 to 1.7 kg., were employed. These were divided into three groups of twelve. Half of the animals in group 1 received no treatment whatever, while the other half received normal physiologic saline. These were used as two sets of controls. Those in groups 2 and 3 received methylglucamine and glucophylline, respectively. For convenience, all animals received equal volumes of the substances injected: the rabbits received 0.2 c.c. for the first period of thirty

*"Normal values" of blood (count and chemistry) reported above are taken from Tables I and III, respectively, from Wagoner, G., and Custer, R. P.: *A Handbook of Experimental Pathology*, Springfield, Ill., 1932, Charles C Thomas.

2. Blood: Studies on blood changes included (1) erythrocytes, (2) white blood cells, (3) differential, (4) nonprotein nitrogen, and (5) creatinine. One complete weekly determination was made on each dog during the fifty-four days of the experimental period. In the case of the rabbits there was one complete weekly determination on each of eight animals, two within each group, the last being made at the time of disposition of the animal for histologic purposes. As with the dogs, the figures appearing in Table III represent the composite averages within each group. Included also in this table, for purposes of comparison, are figures of normal blood values for dogs and rabbits.*

3. Histologic: Tissues fixed in 10 per cent formalin were prepared for microscopic study from both sets of animals. The dogs were all disposed of on their last experimental day (the fifty-fourth); the rabbits were disposed in series of twos at ten-day intervals, beginning with the end of the first experimental period on the thirtieth day. Thus, whereas the first group that were treated had received a single daily dose for thirty days, the second, third and fourth groups received this, followed afterward by a double dose daily at intervals of ten, twenty, and thirty days, respectively. Although these animals were exposed to unequal quantities of the drugs over varying periods of time, no appreciable differences could be demonstrated in the tissues studied. Pulmonary hemorrhages, demonstrable in most samples studied, were due to ante-mortem traumatic injury. Samples of brain, lung, heart, liver, kidney, and spleen were examined (see Table IV).

From these studies it is apparent that glucophylline neither disturbs the growth nor checks the normal increase in the weight of immature rabbits. Furthermore, with respect to both dogs and rabbits no noticeable difference could be observed in the general appearance of treated and untreated animals regarding health and general state of nutrition. In these respects all the groups exhibited the same general condition of health. The microscopic study revealed the presence of cloudy swelling as a rather constant finding in samples taken from both dogs and rabbits. This finding was quite as conspicuous in the tissues of animals used as controls, as it was in those of animals treated with methylglucamine and glucophylline. The blood samples taken from our rabbits showed an inordinately high differential eosinophilic count. This phenomenon is a matter of not uncommon occurrence in the blood of laboratory animals. It is very probable that these cells, or many of them, were pseudo-eosinophiles or emphophiles. Referring to this type of cell. Wagoner and Custer[2] make the observation that "the analogue of the human neutrophile varies only in that the granules are larger than neutrophilic granules and take the acid stain by preference, although there is a slight affinity for the basic dye." Since this eosinophilic condition was uniformly present in each group, treated as well as untreated, we felt that we were dealing with cases of pseudo-eosinophilia and that these findings, therefore, were probably of no pathologic significance. Indeed, many a laboratory animal that appears to be normal and healthy in every respect has been found to exhibit visceral lesions exposed by the microscope, if not grossly visible at autopsy. In the course of these studies one of

*Taken from figures compiled by Wagoner and Custer and reproduced in Tables I and III, pages 33 and 34 of their *Handbook of Experimental Pathology*, Springfield, Ill., 1932, Charles C Thomas.

18. Rabbit C-5	No change	Hyperemia, few small hemorrhages	Cloudy swelling; small hemorrhages	Cloudy swelling	Marked cloudy swelling; hyaline casts in collecting tubules	Slight hyperplasia

the female dogs in our kennels gave birth to a litter of six pups. On the day after birth we began giving daily injections of glucophylline to three of these pups, using the other three as controls. No significant differences have been noticed, and at the end of thirty days the relative individual weights have shown uniform increases.

SUMMARY

Laboratory studies on dogs and rabbits treated with methylglucamine and glucophylline revealed:

1. Growth of immature rabbits is not disturbed. These animals made increases in size and weight commensurate with normal controls.
2. The dogs, treated and controls, all lost weight—a condition due probably to food and housing restraint.
3. Histologic study of brain, heart, lung, spleen, kidney, and liver of both dogs and rabbits showed no harmful effects that might be attributed to the drug.
4. Significant figures setting forth results are appropriately tabulated.

We wish to express thanks to Dr. Robert S. Jason and Dr. Bernard Kapiloff for personal assistance, and, to the Abbott Laboratories for providing the drugs used in these experiments.

CARCINOMA OF STOMACH DEVELOPING IN PERNICIOUS ANEMIA*

LEWIS H. BRONSTEIN, M.D., NEW YORK, N. Y.

THE combination of pernicious anemia and carcinoma of the stomach in one patient tends to rouse our curiosity as to the possible relationship between the two diseases. This inquisitiveness becomes more marked when one treats a patient for pernicious anemia and years later finds that that person has a carcinoma of the stomach. Many questions and possibilities arise. The following case is being reported as one that raises the discussion again. It is that of a patient who was treated for pernicious anemia for four and one-half years, at the end of which time an extensive carcinoma of the stomach was found. Table I shows the results of the various blood studies that were done during his course of treatments.

T. K., a 45-year-old Greek male, an unemployed kitchen helper, was admitted to the surgical service on Jan. 19, 1936, with a history of a mass in the right scrotum for some time. This suddenly became large and painful.

Examination revealed a tender scrotal mass, 7 by 6 by 5 inches, which transilluminated light and was moderately tender. There was discoloration of the distal third, the color being different from the remainder of the scrotum, suggesting to the surgeon that something recent had happened to it. Although the patient appeared pale, with a questionable lemon-yellow tint to the skin, immediate operation was decided upon. This was done under local anesthesia and a hydrocele with old and recent hemorrhages was found. The surgical condition cleared uneventfully.

The medical service then took over. The blood studies revealed a hyperchromic macrocytic anemia, as can be seen from the figures in the first line in Table I. The platelet count was normal. The red blood cell fragility test showed a slight increase in resistance, the figures ranging from 0.46 per cent sodium chloride to 0.28 per cent. The icteric index was 15. The sternal bone marrow was studied by Dr. Nathan Rosenthal, hematologist at the Mt. Sinai Hospital, who stated that the case was one of pernicious anemia. The Wassermann reaction was negative.

The gastric contents had no free hydrochloric acid on two occasions, histamine being used as a stimulant both times. They were of a heavy and mucoid character, with a total acid ranging from 7 to 12. No lactic acid was found. The benzidine test for blood was slightly positive on one occasion, but this was felt to be due to the trauma of passing the large stomach tube. Traces of urobilinogen were found in the urine. Stool examination did not show any occult blood, ova, or parasites.

The patient was treated with parenteral liver extract and a reticulocyte response of 12 per cent was obtained on the fifth to sixth day. It had varied from 0 to 1 per cent before the onset of treatment. A steady rise in the hemoglobin and red blood cell count took place. On discharge from the hospital on Feb. 26, 1936, the red cell count was 3,690,000 and the hemoglobin was 58.8 per cent. The cell volume index had dropped from 1.34 to 0.92. The icteric index had also dropped to 5.5 units.

*From the Medical Service, Beekman Hospital, New York City, Dr. Arthur H. Terry, Jr., Director.

Received for publication, May 9, 1942.

During his numerous visits to the clinic difficulties were encountered in trying to get cooperation, but these were mainly due to language differences. He was given biweekly, weekly, and monthly injections for the next four years, depending on the judgment of the physician who saw him in the medical clinic.

A neurologic examination was ordered as a routine procedure on Jan. 12, 1937, and the following findings were recorded: There was a loss of the pupillary light reflex. The biceps and triceps reflexes were diminished. There was a questionable diminution in vibratory sense along the shin bones and toes. A diagnosis of spinal cord disease, probably due to pernicious anemia, was made. However, a spinal fluid Wassermann was requested in order to rule out tabes dorsalis. This was done on Feb. 17, 1937, and the fluid showed a negative Wassermann and a normal colloidal gold curve. On Oct. 11, 1938, one and one-half years later, another neurologic examination was performed to determine the progress of the case, since liver extract had been given in the interim. This showed the pupils to react slightly to light. The biceps and triceps reflexes were still diminished. General sensory examination was negative. The conclusion was that there was probably no spinal cord disease.

The patient never had any complaints during his visits to the out-patient department. He suffered from the usual vicissitudes of existence in a slum, such as difficulty in obtaining extra food allowances. He was bitten by a dog in October, 1937, for which he was treated in the surgical out-patient department. In 1938 and 1939 he had all his upper teeth extracted and had to wait long for an upper dental plate. The plate proved to be a poor restoration and numerous repairs had to be made. During this period he had difficulty in eating a full diet and he lost some weight. His weight dropped from an average of 127½ pounds to 122½. However, in late 1939 and early 1940 his weight returned to its original figure.

In a two-week period in June, 1940, his weight dropped to 112 pounds, the lowest it had ever been. He was, therefore, watched closely, and by July his weight had decreased to 109 pounds. At this time some vague epigastric complaints were elicited by the physician in the medical clinic. In the gastrointestinal clinic he told the physician that he had had some epigastric pain for about two months. An x-ray of the stomach was ordered, and it indicated a large new growth in the middle portion of the stomach, on its greater curvature side (see Fig. 1).

At first he refused admission to the hospital but he later consented to enter. The weight at that time was 107½ pounds. Physical examination showed only emaciation and pallor. The blood showed hypochromic anemia, as seen by a red blood cell count of 2,880,000 and a hemoglobin of 40 per cent. A gastric analysis showed the free hydrochloric acid to be absent. Lactic acid was present. A four-plus reaction for blood was obtained. The stools were consistently positive for occult blood.

Exploratory laparotomy was advised in the hope that an operable lesion would be found. The patient refused this and left the hospital. The social service department kept an eye on him since he refused to return to the out-patient department for check-ups. He was admitted to Bellevue Hospital on Dec. 2, and died on Dec. 11, 1940.

AUTOPSY PROTOCOL

The autopsy protocol was furnished through the kindness and cooperation of Dr. Douglas Symmers, Director of Pathology, Bellevue Hospital:

The examination of the gastrointestinal tract reveals the lower one-third of the esophagus to be infiltrated with tumor tissue. The lumen is not constricted. The tumor tissue invades the mucosa and the underlying tissue of the esophageal wall. This tumor mass extends by direct continuity with the tumor growth seen in the stomach. There is no distention of the esophagus above the tumor site. The stomach is constricted in its midportion, resembling an "hourglass." On opening the stomach the lumen is found to contain a large amount of clotted blood. There is seen an ulcerating and fungating tumor mass which extends from the greater curvature over the entire posterior surface and around to the lesser margin of the stomach, leaving the anterior surface of the stomach free of tumor tissue.

Microscopic examination of the stomach tissue showed one part of the section to be replaced completely by tumor tissue. This tumor tissue extends from the mucosa, invades the underlying submucosa, muscularis, and serosa. Only small remnants of the aforementioned tissue are present. The tumor cells assume, for the most part, no set arrangement. Some, however, tend to assume a papillary form, and others, an acinar formation. The cells have no definite shape. They are fairly large cells with scant amount of eosinophilic cytoplasm and a large central oval vesicular nucleus with large nucleoli. Many mitotic figures are seen. Some of the tumor tissue has undergone necrosis.

The tail of the pancreas was found to be invaded for a short distance by the stomach tumor. Metastatic nodules were found in the liver, left adrenal, and surrounding lymph nodes. Microscopic examination showed this tissue to be similar to that in the stomach. No tumor cells are noted in the bone marrow. The different blood cells are present in their normal numbers.

The final diagnosis was as follows: Carcinoma of the gastrointestinal tract; fungating and ulcerating carcinoma of the stomach with hourglass constriction and hemorrhage into the lumen; extension into liver, pancreas, and esophagus; and metastases to mesenteric lymph nodes, liver, and left adrenal; moderate coronary atherosclerosis; mild atherosclerosis of the aorta; focal adhesive pleuritis; mild congestion of the liver; and general emaciation.

DISCUSSION

This case raised several interesting questions. One was whether or not this patient had had carcinoma of the stomach at the original discovery of his hyperchromic macrocytic anemia. The anemia was discovered accidentally when he was admitted to the hospital for a hemorrhage into a hydrocele. He had no complaints referable to his gastrointestinal tract. The only disconcerting fact was that he did not have an atrophic tongue. However, the various factors in the blood examination, such as color index, mean corpuscular volume, mean corpuscular hemoglobin, and bone marrow smears seemed to point to a diagnosis of pernicious anemia. The achlorhydria was a confirming factor, as were also the icteric index of 15 units and the response to liver treatment. The absence of occult blood in the stool at his first examination made us believe that there was no point in doing an x-ray of the gastrointestinal tract merely as a routine. This point, of course, cannot be settled in this patient. The type of carcinoma that was found, namely, a fungating, adenocarcinoma in the fundus of the stomach in the greater curvature side, has been called the "silent type" because it does not produce symptoms till very late in the course of the disease. It is still possible, therefore, that it might have been present all the time.

Some patients have been reported in the literature in whom gastric complaints have appeared during the course of pernicious anemia and in whom gastrointestinal x-rays were reported as showing no pathology. Subsequently, these patients developed carcinomas in various portions of the stomach. Conner and Birkeland[1] reported three such patients in whom carcinomas were found, respectively, in the esophagus and cardia of the stomach, in the pylorus, and in an unstated site in the third patient. Miller[2] reported two patients in whom carcinomas were found in the pylorus and in the middle portion of the greater

Fig. 1.

and lesser curvatures of the stomach. Of the seven patients reported by Washburn and Rozendaal[3] in whom a clinical diagnosis of pernicious anemia antedated the discovery of the carcinoma of the stomach, four patients had had previous x-rays of the stomach which showed no pathology. One patient had a scirrhous carcinoma of the upper two-thirds of the stomach; the second, a polypoid, ulcerating lesion removed by subtotal gastrectomy; the third, carcinoma of the distal half of the stomach; and the fourth, polypoid carcinoma involving the greater portion of the stomach.

Although no analysis has been made of the patients who had routine x-rays of the stomach, even though no gastrointestinal symptoms were present, it might seem advisable to perform such an examination on any patient who has the symptom complex, pernicious anemia. It, of course, might be advocated to examine any patient with pernicious anemia with a gastroscope, since lesions can be observed earlier with it than with an x-ray examination. However, the value of this procedure has not been demonstrated as yet in this type of case.

Of great interest in the case presented here is the change in the blood picture, which occurred some time before either loss of weight or gastric symptoms could be elicited. The figures in April, 1939, showed a marked drop as compared to the previous calculations. In January, 1940, this was even more marked with a hemoglobin of 68 per cent. At that time a search should have been made for some complications. Some authors[4, 5] have from time to time pointed out the necessity of searching for malignancies when the type of anemia in a treated case of pernicious anemia changes to a normocytic or microcytic form. Whether an operable carcinoma would have been found is a moot point. It is also impossible to state whether any lesion would have been discovered, although the size of the lesion found in July, 1940, makes me feel that some pathology would have been seen in January, 1940.

The literature records very few cases in which the blood count showed the suspicious changes before symptoms appeared. In the greatest majority of reported cases it was the appearance of new symptoms, or the inability to alleviate these complaints with liver therapy, which led to the x-ray studies of the gastrointestinal tract. One of the patients reported by Conner and Birkeland (Case 9)[1] had pernicious anemia for seven years when fresh blood was noted in a gastric analysis. Two x-rays taken two months apart were negative. A blood count done three months after the last x-ray examination, and following an attack of influenza, showed a hemoglobin of 29 per cent and an erythrocyte count of 2 million. Three months later he vomited blood, and an x-ray examination showed an obstructive lesion in the esophagus. Here the blood count changed to a low color index anemia before the x-rays disclosed a definite lesion. Numerous reports[1, 3-6] are present in the literature where a low color index anemia was discovered at the time that the carcinoma was found in the patients with pernicious anemia.

An interesting point and one which can lead to a great deal of speculation is to be found in the bone marrow studies. A bone marrow puncture, performed at the beginning of the observation, showed the cells to be typical of pernicious anemia. Nevertheless, study of the bone marrow at autopsy revealed no apparent changes.

CONCLUSIONS

A case of pernicious anemia is reported in which a carcinoma of the stomach was found four and one-half years after the initial diagnosis was made. Of particular interest is the fact that blood studies showed a change in the type of anemia several months before signs or symptoms of the carcinoma were found. It is suggested that blood studies be done repeatedly on patients with pernicious anemia and that a prompt search for pathology be made should a change in the character of the anemia be found.

CLINICAL CHEMISTRY

GUANIDINE AND ITS RELATIONSHIP TO MUSCULAR DYSTROPHY*

Robert P. MacFate, Ch.E., M.S., Ph.D.
Chicago, Ill.

THE abnormal metabolism of creatine (methylguanidine acetic acid) in progressive muscular dystrophy and certain other muscle conditions, as reported by Levene and Kristeller,[1] Brand and his co-workers,[2] Magee,[3] Thomas, Milhorat, and Techner,[4] Milhorat,[5] Tripoli and Beard,[6] and others, led me to study the effects of the administration of simple guanidine salts on creatine metabolism. It was first thought that administered guanidine might give rise to an added production and excretion of creatine. As the experiments progressed, the results suggested that the increased excretion of creatine following guanidine administration and in nutritional muscular dystrophy was due to changes produced in the muscle rather than to a direct production of creatine from the added guanidine.

MINIMUM LETHAL DOSE OF GUANIDINE HYDROCHLORIDE AND METHYLGUANIDINE SULFATE

Guanidine hydrochloride and methylguanidine sulfate were chosen for study. The minimum lethal doses of these compounds were determined to serve as a basis for their administration. The minimum lethal dose (M.L.D.) was defined as the number of milligrams of guanidine salt per gram of body weight which would cause the death within twenty-four hours of one or more of a series of fasting animals.

Guanidine hydrochloride and methylguanidine sulfate were administered intramuscularly and by stomach tube in a 5 per cent aqueous solution to healthy guinea pigs that had fasted twenty-four hours. The findings at the chosen end points are shown in Table I. Guinea pigs receiving the M.L.D. of either guanidine salt became nervous, showed varying degrees of trembling and twitching, and finally went into convulsions and died. Guinea pigs receiving less than the M.L.D. showed varying degrees of nervousness, trembling, and twitching, depending on the amount of guanidine salt given. Death occurred in some of the guinea pigs in this latter group, but later than twenty-four hours after the administration of the guanidine.

PROTECTIVE ACTION OF GLYCINE

Schmeideberg and Bunge[7] were among the first to show that benzoic acid is detoxicated in the kidney by conjugation with glycine and then excreted as the less toxic hippuric acid. Since that time it has been found that this synthesis takes place in other parts of the body as well as the kidney. It also has been found that the animal organism protects itself in the same manner from many toxic substances, such as phenylacetic acid, cresols, and others. Perhaps this same mechanism comes into play in the detoxication of simple guanidine salts.

Single and daily doses of 1 mg. of glycine per gram of body weight were found to be nontoxic in healthy guinea pigs. The protective action of this amount of glycine was then studied.

TABLE I

FATALITY OF THE M.L.D. OF GUANIDINE SALTS

GUINEA PIGS USED	SALT ADMINISTERED	METHOD OF ADMINISTRATION	M.L.D. (MG. PER GM. OF BODY WEIGHT)	ANIMALS DIED IN 24 HOURS (PER CENT)
14	Guanidine hydrochloride	Intramuscular	0.24	60
13	Guanidine hydrochloride	Oral	0.40	80
10	Methylguanidine sulfate	Intramuscular	0.29	75
10	Methylguanidine sulfate	Oral	0.50	50

TABLE II

PROTECTIVE ACTION OF SINGLE DOSES OF GLYCINE AND GLUCOSE AGAINST GUANIDINE HYDROCHLORIDE

TOTAL NUMBER OF GUINEA PIGS	GUANIDINE HYDROCHLORIDE	GLYCINE	GLUCOSE	NUMBER OF GUINEA PIGS SURVIVING	PER CENT SURVIVING	AVERAGE BLOOD GLUCOSE IN SURVIVORS, 6 HR. AFTER GUANIDINE (MG. PER 100 C.C.)
11	M.L.D.	No	No	3	27	54
12	M.L.D.	Yes	No	9	75	75
8	M.L.D.	No	Yes	3	38	65

Single doses of 1 mg. of glycine per gram of body weight were given by stomach tube to healthy guinea pigs that had fasted twenty-four hours. One hour later, the M.L.D. of guanidine hydrochloride was administered intramuscularly to 6 of the guinea pigs. The M.L.D. of methylguanidine sulfate was administered intramuscularly to the remaining 6 guinea pigs. All the guinea pigs showed the usual symptoms of guanidine intoxication and the majority died within twenty-four hours. Glycine in single doses, therefore, has no protective action against the M.L.D. of toxic guanidine salts.

The protective action of daily doses of glycine was then studied. Twenty-four guinea pigs were divided into two groups. Group A received daily doses of 1 mg. of glycine per gram of body weight. Group B received no glycine. On the second and following days, one-third M.L.D. of guanidine hydrochloride was administered intramuscularly to 4 guinea pigs of each group, one-third M.L.D. of methylguanidine sulfate was administered intramuscularly to an-

other 4 guinea pigs of each group, and one-third M.L.D. of methylguanidine sulfate was administered orally to the remaining 4 guinea pigs of each group. The amount of guanidine salt in each dose was uniformly increased at regular intervals until four-fifths M.L.D. was being given daily.

The average life of the guinea pigs receiving only the guanidine salts was twenty-eight days; the average life of those receiving glycine in addition was thirty-five days. On long-continued administration of guanidine salts, the guinea pigs appeared to develop a greater tolerance to the drug. However, the guinea pigs receiving glycine showed fewer and milder symptoms of guanidine intoxication and in addition lived longer. It appeared, therefore, that administered glycine aided the animals in overcoming the effects of toxic guanidine salts.

PROTECTIVE ACTION OF GLUCOSE

Watanabe[8] and others found that a severe hypoglycemia developed after the administration of toxic guanidine salts. Frank, Nothmann, and Wagner[9] found that the severity of spasms and the duration of life of animals poisoned by guanidine were dependent upon the amount of carbohydrate available in their organisms. Hummel[10] also noted this protective action of glucose, but Bakucz[11] was not convinced of its effect.

Experiments similar to those above were performed to study the protective action of glucose. The effects of single doses of glucose and of glycine against the M.L.D. of guanidine hydrochloride are shown in Table II. In experiments with daily administration, the average life of the guinea pigs receiving guanidine hydrochloride alone was eighteen days; of the guinea pigs receiving guanidine hydrochloride and glucose, nineteen days; and of the guinea pigs receiving guanidine hydrochloride and glycine, twenty-seven days. Glucose appeared to have no protective action.

EFFECT OF GLYCINE AND GUANIDINE HYDROCHLORIDE ON THE URINE AND MUSCLE CHEMISTRY OF NORMAL GUINEA PIGS

The urine and muscles of guinea pigs were analyzed to serve as controls for comparison with the work to follow on dystrophic guinea pigs. Healthy guinea pigs were placed in small metabolism cages and given a diet of carrots, grain, water, and orange juice. The urine was collected under toluene, measured and filtered daily. The muscles were obtained at death or on sacrificing the animal.

Urine was collected for a ten-day period to serve as a normal. Treatment was then given as shown in Table III. One milligram of glycine per gram of body weight was administered daily at 10 A.M. and 4 P.M. One-third M.L.D. of guanidine hydrochloride was administered at 5 P.M. The amount of guanidine salt in each dose was uniformly increased at regular intervals, as in previous experiments, until four-fifths M.L.D. was being administered daily.

The urines were analyzed for creatine and creatinine,[12] guanidine,[13] and total acid-soluble phosphorus.[14] The results were averaged for the normal period and for the period in which treatment was given. The fresh gastroc-

nemius and gluteus muscles were analyzed for creatine,[15] creatinine,[12] and the acid-soluble phosphorus fractions.[14, 16, 17] The results were averaged and are shown in Table III.

On the administration of glycine alone to normal guinea pigs, the excretion of creatine was increased, probably due to an increased production. An increased concentration of creatine was found in the muscles, although the relative per cent of creatine phosphate changed but little from the normal.

On the administration of guanidine hydrochloride alone to normal guinea pigs, an average of 39 per cent of the guanidine hydrochloride was recovered from the urine. The per cent of guanidine bases excreted decreased as the guanidine hydrochloride administered was increased. There may have been a maximum amount of guanidine that the kidney was capable of excreting or the decreased excretion may have been due to kidney damage. Histologic section of the kidneys showed some damage to the tubules. Some of the guani-

dine may have been converted to creatine, as was suggested by the slight increase in the excretion of creatine. It was more probable, however, that the guanidine hydrochloride either injured the muscle cell or made it more permeable, allowing an excessive loss of creatine to occur, as shown by the low concentration of creatine in the muscle. This loss may have stimulated the muscle or the centers of creatine formation to a greater production of creatine, with a subsequent further loss due to the abnormal permeability of the cell. This suggestion of an increased permeability was further supported by the loss of phosphates from the muscle and the decrease in the relative per cent of creatine phosphate.

On the administration of glycine with the guanidine hydrochloride, the excretion of creatine was increased, the effect being greater than when either glycine or guanidine hydrochloride were given alone. An average of 31 per cent of the guanidine hydrochloride administered was recovered from the urine. This was less than where the guanidine hydrochloride was given alone, and indicated that the glycine probably aided in the detoxication of the guanidine hydrochloride. This detoxication prevented the profound action of the guanidine hydrochloride on the muscle, as shown by the improved muscle metabolism and by the analysis of the muscle. The creatine and total phosphorus of the muscle and the relative per cent of creatine phosphate more nearly approached the normal.

EFFECT OF GLYCINE AND GUANIDINE HYDROCHLORIDE ON THE URINE AND MUSCLE CHEMISTRY OF GUINEA PIGS WITH NUTRITIONAL MUSCULAR DYSTROPHY

Goettsch and Pappenheimer[15] found that a diet composed of rolled oats, wheat bran, casein, lard, cod-liver oil, sodium chloride, and calcium carbonate, treated with ethereal ferric chloride, to which was then added skimmed milk powder, led to a progressive, highly selective and ultimately fatal dystrophy of the voluntary muscles. They found guinea pigs and rabbits to be susceptible and rats to be resistant. This diet is complete in known requirements except for vitamin E. However, Goettsch and Pappenheimer found that the addition of this factor did not prevent the development of the disease. The lesions were not due to inanition, infection, or scurvy, and must be referred to some still unknown factor.

A muscular dystrophy was developed in several litters of guinea pigs. Visible symptoms of muscular dystrophy were shown by the sluggish actions of the guinea pigs, difficulty in righting themselves when placed on their backs, inability to use their hind legs, and finally, inability to rise when placed on their sides. When definite symptoms of muscular dystrophy appeared, the weight had reached a plateau and in most cases was decreasing.

As previously noted, there occurs an abnormal metabolism of creatine in certain muscular dystrophies. Accordingly, the effects of glycine and toxic guanidine salts were studied in dystrophic guinea pigs.

Thirty-one dystrophic guinea pigs were divided into 4 groups. The dystrophy diet was continued. Group 1 was given no additional treatment. Group 2 was given 1 mg. of glycine per gram of body weight daily. Group 3 was given one-third M.L.D. of guanidine hydrochloride daily. Group 4 was given both

glycine and guanidine hydrochloride according to the amounts previously noted. The amount of guanidine salt in each dose was uniformly increased at regular intervals, as in previous experiments. The experiment was continued to the death of the guinea pigs. The chronologic data are shown in Table IV.

Twelve dystrophic guinea pigs were divided into 4 groups. They were placed in small metabolism cages, and the dystrophy diet and orange juice were continued. The urine was collected under toluene, measured and filtered daily. Urine was collected for seven days after dystrophy developed to serve as a control period. Treatment was then given these 4 groups as detailed for the preceding 4 groups.

TABLE IV

EFFECT OF GLYCINE AND GUANIDINE HYDROCHLORIDE ADMINISTERED TO GUINEA PIGS WITH NUTRITIONAL MUSCULAR DYSTROPHY

TREATMENT	NO. OF GUINEA PIGS	AGE AT START OF DYSTROPHY (DAYS)	AGE AT TIME OF MARKED DYSTROPHY (DAYS)	INTERVAL FROM START TO MARKED DYSTROPHY (DAYS)	AGE AT DEATH (DAYS)	INTERVAL FROM START OF DYSTROPHY TO DEATH (DAYS)
None	7	94	103	9	110	16
Glycine	8	95	106	11	116	21
Guanidine hydrochloride	8	93	98	5	103	10
Glycine and Guanidine hydrochloride	8	97	105	8	112	15

The urines were analyzed as already detailed, and the results were averaged for each period of the experiment. The fresh gastrocnemius and gluteus muscles were analyzed as detailed. The results were averaged and are shown in Table V.

The guinea pigs in which a nutritional muscular dystrophy was developed excreted a larger amount of creatine than did normal guinea pigs. This may have been due to defective storage, to degeneration of the muscle tissue, or to a greater production. It is probable that all three mechanisms were involved. Dystrophic guinea pigs also excreted a smaller amount of creatinine as the dystrophy developed, probably due to the decreased creatine metabolism. Guanidine excretion was increased, probably due to defective metabolism of these compounds. The production of toxic guanidine compounds in the muscle cell may have lowered the permeability of the cell, thus accounting for the loss of creatine from the muscle and its increased excretion. An initial larger excretion of phosphorus was followed by a decreased excretion, indicating a probable loss of phosphorus compounds from the muscle. These findings were confirmed by the muscle analysis.

Glycine appeared to have some effect in delaying the progress of nutritional muscular dystrophy. Clinically, the animals appeared more normal and their span of life was increased. An increased excretion of creatine was noted and an increased concentration was found in the muscle. This increased concentration of creatine was responsible, probably, for the better functioning of the muscle and for the delay in the progress of the dystrophy.

The toxic effects of guanidine hydrochloride were more pronounced in dystrophic guinea pigs than in the normal. Glycine appeared again to reduce

its toxicity. On the administration of guanidine hydrochloride to dystrophic guinea pigs, an average of 63 per cent of the guanidine hydrochloride was recovered from the urine. These figures were markedly higher than those obtained with normal guinea pigs, indicating a defect in the metabolism and detoxication of these substances.

EFFECT OF GLYCINE AND GUANIDINE HYDROCHLORIDE ON THE BLOOD, URINE, AND MUSCLE CHEMISTRY OF NORMAL DOGS

In the previous experiments the small size of the guinea pigs prevented extensive blood, urine, and muscle examinations. Dogs were adopted, therefore, as the test animal. Guanidine hydrochloride was used since it showed a greater toxicity than did methylguanidine sulfate. The compound was administered intramuscularly as it exerted a more profound effect in this manner.

The blood, urine, and muscles of 16 dogs were analyzed to serve as controls for comparison with the work to follow on dystrophic dogs. Healthy dogs were placed in metabolism cages and given the normal diet of meat and meal, with water ad lib. They were weighed twice a week. Urine was collected under toluene, measured and filtered daily. Blood was drawn twice a week. The muscles were obtained at death or on sacrificing the animal. Urine and blood were collected for a period of two weeks to serve as a normal. Treatment was then given as shown in Table VI.

One milligram of glycine per gram of body weight was administered daily by capsule. Eight-tenths milligram of guanidine hydrochloride per gram of body weight was injected intramuscularly one hour after the glycine. After three weeks the glycine and guanidine were increased to one and one-half times the original dose; after another two weeks, to two times the original dose; and after another two weeks, to two and one-half times the original dose. This latter dosage was continued to the death of the animals receiving guanidine hydrochloride.

The dogs receiving guanidine hydrochloride alone showed signs of guanidine intoxication after about the second week. They were nervous and showed trembling, which passed on to tetanic twitchings, convulsions, and death. The average life of these dogs was twenty-four days. The dogs receiving both glycine and guanidine hydrochloride were nervous and showed trembling and tetanic twitchings only two to three days before death. There were no other signs of intoxication over the period of the experiment. The average life of these dogs was forty-seven days.

The blood specimens were analyzed for sugar,[19] nonprotein nitrogen,[20, 21] creatine and creatinine,[22] amino acids,[23] guanidine,[24] inorganic and total acid-soluble phosphorus,[14] and lactic acid.[21, 25] The urines were analyzed for total nitrogen,[20, 21] creatine and creatinine,[12] guanidine,[13] and inorganic and total acid-soluble phosphorus.[14] The results were averaged for each period of the experiment. Table VI shows the average findings during the normal period and during the period of maximum dosage where the most striking changes were noted. Mixed samples of gastrocnemius, anterior tibialis, and biceps and quadriceps femoris were analyzed for creatine,[15] creatinine,[12] guanidine,[13, 26] acid-soluble phosphorus fractions,[14, 16, 17] sodium,[27, 28] potassium,[29] calcium,[27] chlorine by a modified silver nitrate and thiocyanate titration, and water content by drying to constant weight. The average results are shown in Table VI. Muscle and kidney specimens were examined histologically.

The muscles of the normal dogs and those receiving glycine were grossly and microscopically normal. The muscles of the dogs receiving guanidine hydrochloride alone showed many swollen and granular areas with a marked nuclear reaction. The muscles of the dogs receiving glycine and guanidine hydrochloride were normal grossly. Microscopically, a few swollen fibers were seen showing a marked nuclear reaction. The kidneys showed some damage to the tubules.

The oral administration of glycine to normal dogs produced an increased excretion of creatine. No other change was noted other than the increased blood amino acid concentration and an increased excretion of nitrogen which were to be expected.

The administration of guanidine hydrochloride to normal dogs produced an increased excretion of creatine. The greatest rate of excretion was found to occur in the first week or two of guanidine administration. It was probable, therefore, that the guanidine injured the muscle cell or lowered its permeability, allowing creatine to diffuse more rapidly than normal. The muscle was found to have a decreased creatine content, a decrease in the total acid-soluble phosphorus, and both a relative and an absolute decrease of creatine phosphate. A decrease in the blood sugar and an increase in the lactic acid showed a disturbance of the carbohydrate metabolism. An increased nitrogen retention was noted. A decrease in the potassium and an increase in the sodium and chlorine of the muscle showed a profound disturbance in the electrolyte balance. Guanidine bases were increased throughout, due to their administration.

The administration of glycine with the guanidine reduced the toxic action of the latter. The large supply of glycine aided directly in the detoxication and also promoted the production of creatine to replace that lost from the muscles. Metabolism in general appeared to be more normal. A nitrogen retention was still present, but less severe disturbances of carbohydrate metabolism and electrolyte balance were noted.

EFFECT OF GLYCINE AND GUANIDINE HYDROCHLORIDE ON THE BLOOD, URINE, AND MUSCLE CHEMISTRY OF DOGS WITH NUTRITIONAL MUSCULAR DYSTROPHY

A partial nutritional muscular dystrophy was developed in dogs. The dogs were weaned when they were forty-two days old and were placed in metabolism cages. The diet of Goettsch and Pappenheimer[18] was used. Sufficient water was added to the food to make a moist mass. This diet was supplemented by the use of additional skimmed milk powder dissolved in water, with the addition of vitamins A, C, and D. Water was allowed ad lib.

Morgulis and Spencer[30] found that the development of a nutritional muscular dystrophy following the diet of Goettsch and Pappenheimer could be prevented by the addition of whole wheat germ to the dystrophy-producing diet. Two dogs were placed on the diet with 10 per cent wheat germ added.

The dogs were weighed, and blood and urine were collected at two-week intervals during the first part of the experiment.

Visible symptoms of muscular dystrophy did not appear as rapidly nor was the dystrophy as pronounced as in the guinea pig. In about five months the weight had reached a plateau. Less interest was shown in food and the dogs appeared listless much of the time. A definite weakness finally appeared in the hind legs. Many of the animals died of pneumonia. These dogs were not included in the average findings given here.

When definite signs of weakness appeared in the hind legs, the dogs were weighed twice a week, urine was collected under toluene daily, blood was drawn twice a week, and the muscles were obtained at death or on sacrificing the animal. Treatment was then instituted as noted in Table VII.

The same amounts of glycine and guanidine were given as detailed above. After three weeks they were regularly increased as previously noted.

Blood and urine specimens were analyzed as previously discussed and the results were averaged for each period of the experiment. Table VII shows

the average findings for the dogs in each group during the period when they were on the dystrophy diet alone and appeared to be normal clinically; during the period of slight dystrophy, as shown by slight weakness; and during the period of marked dystrophy, as shown by marked weakness before death. The muscle specimens were analyzed as already described, and histologic sections were made. The results of the chemical analyses are shown in Table VII.

At autopsy the muscles of the thighs and hind legs of the dogs, which showed marked weakness before death, were found to be pale in color and flabby. Areas of damaged fibers were seen. Many were swollen, showing degeneration and a marked nuclear reaction. A moderate infiltration with fibrous tissue was seen. The muscles of the dogs receiving 10 per cent wheat germ were normal.

Little metabolic change was noted until the muscular dystrophy became evident clinically. A slight increase in the excretion of creatine was noted, seen more especially in the daily analyses than in the averages shown. When marked muscular dystrophy developed, a further increase was noted in the excretion of creatine, accompanied by an increased excretion of total acid-soluble phosphorus. A low blood creatine concentration finally developed and a low concentration of creatine and creatine phosphate were found in the muscles. An increased concentration of guanidine base was found in the blood, urine, and muscle. The increased concentration of guanidine in the muscle may have produced an increased permeability, with the resulting loss of creatine and phosphate. The increased guanidine was due, probably, to some defect in the metabolism of guanidine compounds. A disturbance also was seen in the carbohydrate and mineral metabolism, similar to that seen in the normal dogs when toxic guanidine compounds were injected intramuscularly.

Glycine appeared to delay the effects of the nutritional muscular dystrophy, as shown by the blood, urine, and muscle chemistry. The animals lived longer and their metabolism was more normal. The basis of this improvement may have been the increased concentration of creatine in the muscle due to its increased production.

Guanidine hydrochloride showed a greater toxicity in dogs suffering from a nutritional muscular dystrophy than it did in normal dogs. Glycine again aided in the detoxication of this added guanidine.

DISCUSSION

The administration of toxic guanidine salts over a period of several weeks results in a loss of creatine and phosphate from voluntary muscle. It appears probable that guanidine increases the permeability of the muscle cell, allowing creatine and phosphate to diffuse more rapidly than normal when they have been separated during muscular action. This suggestion is supported by the work of Gavrilescu,[31] who found by conductivity experiments that guanidine compounds increased the permeability of abdominal muscles. The lowered concentration of creatine in the muscle may stimulate the centers of creatine production, resulting in an increased production and further loss of creatine.

Increased blood guanidine and increased guanidine excretion have been noted in many conditions. Much confusion has resulted from the attempt to

associate various clinical symptoms with the level of blood guanidine. It is suggested that blood guanidine is the result, and not the cause, of endogenous guanidine intoxication. A guanidine derivative produced in any tissue may exert a more profound action in that tissue than it may exert after diffusion into the extracellular body fluids. The level of the blood guanidine probably depends on the activity of the centers of detoxication.

In exogenous guanidine intoxication other physiologic effects of guanidine may overshadow its action on the muscle cell. This effect is increased by the apparent ability of the animal to acclimate itself to larger amounts of administered guanidine over a period of time.

There is a similarity in the blood, urine, and muscle chemistry of guanidine intoxication and of nutritional muscular dystrophy. The increased concentration of simple guanidine compounds in nutritional muscular dystrophy suggests the possibility that these compounds may be the cause of the metabolic disturbance in this condition. The increased concentration of guanidine in the blood and urine of patients with progressive muscular dystrophy, as found by MacFate,[32] Sullivan, Hess, and Irrevere[33] and others, and the similarity of the muscle findings in this paper to the findings in progressive muscular dystrophy, as reported by Nevin,[17] Reinhold and Kingsley,[34] and others, suggest the possibility that toxic guanidine compounds may be responsible for, or at least initiate, the abnormal processes found in progressive muscular dystrophy and other dystrophies accompanied by like metabolic changes.

Hines and Knowlton[35] believe that the findings of altered concentration of various substances in atrophic muscles can be attributed to relative changes in the amounts of muscle cell and nonmuscle cell phases rather than to a change in the composition of the various phases. They found the increase in chloride concentration of atrophied muscle (from denervation, fasting, and tenotomy) to parallel the extent of atrophy and the relative increase in connective tissue, and, therefore, concluded that the chlorides of the muscle are chiefly associated with the connective tissue. Morgulis and Osheroff[36] state that at least a part of the chloride is a component of the connective tissues and that the increase in chloride content of dystrophic muscles is undoubtedly associated with the increase in fibrous tissue. The moderate increase in connective tissue noted in these experiments may account, in some degree, for the chemical changes observed. However, microscopic study did not reveal as great an increase in the connective tissue as is usually seen in cases of atrophy from denervation, fasting, and tenotomy. Further, because of the rapid and early chemical changes noted, it is believed that some other factor, such as an increased permeability of the muscle cell, must be considered.

The therapeutic value of glycine in these conditions probably lies in its stimulation of an increased production of creatine. This may be due to the specific dynamic action of the glycine itself (Rapport and Katz[37]). An increased glycine concentration in the blood and body fluids may stimulate the production of large amounts of creatine until the creatine production centers adjust themselves to this new and increased level of glycine. The rate of creatine production may then drop to approximately normal, accounting for the decreased excretion of creatine found in many patients after glycine therapy

over a long period of time, as reported by Thomas, Milhorat, and Techner,[4] Milhorat,[5] and others. The value of glycine in the treatment of progressive muscular dystrophy apparently depends upon the ability of the muscle cell to utilize the creatine produced. This ability appears to be lost gradually as the muscular dystrophy progresses.

The toxicity of guanidine derivatives varies greatly (Alles[35]). The general finding of increased blood guanidine cannot be properly evaluated until methods are perfected for determining the exact guanidine derivative present.

CONCLUSIONS

1. The daily administration of one-third to four-fifths M.L.D. of a toxic guanidine salt, over a period of several weeks, produces changes in the metabolism and structure of the muscle, similar to those found in nutritional muscular dystrophy and in progressive muscular dystrophy. There are produced a loss of creatine and phosphate from the muscle and severe disturbances in carbohydrate metabolism and the electrolyte balance. It is suggested that guanidine may lower the permeability of the muscle cell, producing these changes.

2. One milligram of glycine per gram of body weight, administered daily, appears to afford some protection against small daily doses (one-third to four-fifths M.L.D.) of a toxic guanidine salt.

3. Glycine delays the progress of a nutritional muscular dystrophy.

4. It is suggested that the abnormal metabolism of guanidine compounds may be an etiologic factor in the production of a progressive muscular dystrophy.

A COMPARATIVE STUDY OF DEXTROSE AND DEXTRIN TOLERANCE IN PATIENTS WITH CHRONIC ULCERATIVE COLITIS*

ROBERT C. PAGE, M.D., Z. BERCOVITZ, M.D., AND EDWIN J. DE BEER, PH.D.
NEW YORK, N. Y.

ABSORPTION studies in chronic ulcerative colitis have been confined mainly to dextrose, and it seemed of interest to us to study the intestinal absorption and the blood sugar response of another carbohydrate. For this study, a mixture of polysaccharides (dextrins and maltose) produced by the partial breakdown of starch was selected. For control purposes dextrose absorption was studied simultaneously. Tolerance curves served as a measure of the absorption process.

Low or flat blood sugar curves for oral dextrose tolerance tests have been frequently found by us (Z. B. and R. C.P.)[1] in patients with chronic ulcerative colitis. In one group of 58 standard oral, one dose, two-hour dextrose tolerance tests, 23 (39.6 per cent) tests were of the low or flat type. Groen,[2] using a simplified technique of intestinal intubation, ascribed the decreased absorption of dextrose to a defect in the absorptive capacity of the intestinal wall and not to an unusually rapid passage of the intestinal contents.

METHOD OF STUDY

Twenty-three patients with chronic ulcerative colitis attending an outpatient clinic were studied. All the patients had had the disease for periods of one or more years.

Both the oral dextrose tolerance test and the oral dextrin tolerance test were carried out on the same patient. These tests were alternated in successive patients. The tests were carried out from six to ten days of each other, with no change in diet, so that each patient served as his own control.

The patients reported in the morning without breakfast. They were weighed and a fasting venous blood sample was obtained. One gram per kilogram of body weight of dextrose or dextrin† in 150 to 200 c.c. water was given, and blood samples were taken at one-, two- and three-hour intervals, and in some instances at four and five hours. Urine was also collected and examined for dextrose at these intervals. The venous blood was analyzed for true dextrose content by the Shaffer-Somogyi[3] method. The results, therefore,

†Since pure dextrin was found unsuitable because of unpalatability and difficulty of making acceptable solutions, "Dexin" (Burroughs Wellcome & Co.), containing 75 per cent dextrins and 24 per cent maltose, 0.75 per cent moisture, and 0.25 per cent mineral matter, was used. Since the predominant constituent of this polysaccharide and disaccharide combination consists of dextrin, we have used the term *dextrin* in the text to denote this dextrin-maltose preparation.

Urinalyses on the entire group of patients using quantitative Benedict's test revealed reducing substances in only one patient (No. 8). The fasting specimen was negative, and in the first-hour specimen after oral dextrose the reducing substances were present to the amount of 1.65 Gm., after the second hour 1.13 Gm., and after the third hour 0.45 Gm. In the dextrin test the fasting specimen was negative. After one hour the urine contained 0.59 Gm. of reducing substance, after the second hour 0.45 Gm., and after the third hour 0.19 Gm.

DISCUSSION OF RESULTS

The foregoing observations apparently indicate that at all points the blood sugar levels were higher after the dextrins than after the dextrose. However, it is well known that because of the many variables involved, blood sugar curves undergo wide fluctuations. Therefore, a statistical analysis of the results was made in order to determine whether the greater hyperglycemia following the dextrin administration was real or whether it was only an accident due to chance.

Statistical Analysis.—The dextrin and the dextrose curves were compared by calculating the statistic "t" for the differences in the blood sugar means at the one-hour, two-hour, and three-hour periods. The respective "t" values found were 5.568, 3.846, and 2.756, and the corresponding probabilities, as given by the tables of Fisher and Yates,[4] were $P = <0.001$, $P = <0.001$ and $P = >0.001$ but <0.01. Since a probability of $P = 0.001$ indicates one chance in 1,000 and a probability of $P = 0.01$ indicates one chance in 100, one may conclude the difference is real and that dextrin administration produced higher blood sugar values than did dextrose administration.

Since 100 mg. of the dextrin mixture are theoretically capable of giving approximately 108 mg. of dextrose if completely hydrolyzed, an approximate correction was made by reducing the mean difference by 8 per cent and again calculating the "t" values. This procedure did not appreciably alter the results.

One hundred milligrams of the dextrin preparation used in this study contained 75 mg. of dextrin, $(C_6H_{10}O_5)_n \cdot H_2O$, which if completely hydrolyzed would yield 83.3 mg. of dextrose (using the factor of 0.9, since nine parts of dextrin give ten parts of dextrose upon hydrolysis),[5] and 24 mg. of anhydrous maltose $(C_{12}H_{22}O_{11})$, which would yield 25.2 mg. of dextrose (using the factor of 0.95) if completely hydrolyzed, making a total of 108.5 mg. of dextrose. Actually the maltose is present in the hydrated state $(C_{12}H_{22}O_{11} \cdot H_2O)$ so that 24 mg., when hydrolyzed, yields 24 mg. of dextrose (1.2 mg. less than with anhydrous maltose). Using this figure in the calculation, 100 mg. of the dextrin-maltose mixture would yield 107.3 mg. of dextrose instead of 108.5 mg. We have compromised between these two values and assume that 100 mg. of the dextrin mixture would be converted into 108 mg. of dextrose, or an 8 per cent increase over the original weight.

The possibility exists that a comparison of the areas under the blood dextrose curves may present a more comprehensive picture than comparisons made separately at three different points. Accordingly, the areas under the 46 curves were measured with a polar planimeter. Areas below a base line passing through the fasting level were considered negative. These data were subjected to an analysis of variance following the standard procedure, such

represent dextrose content with only little interference from other reducing substances (vitamin C, glutathione, methionine, cysteine, etc.).

RESULTS OF STUDY

The results are given in Table I and are presented graphically in Figs. 1 and 2. It will be observed that after dextrose administration the blood sugar at the end of the first hour had risen sharply to an average value of 115 mg. per 100 c.c., an increase of approximately 42 per cent over the average fasting level of 81 mg. per 100 c.c. However, at the end of the second hour it had dropped sharply to 86, being then only 7 per cent above the fasting level. At the end of the third hour it had fallen to 73, or 10 per cent below the fasting level. At the end of the fourth hour the lowest value was reached, 69, or 15 per cent below the fasting level. The four determinations available at the fifth hour showed that blood sugar was starting to recover, now being 75, or 7 per cent below the fasting level.

Means	80.9	114.9	86.3	73.0	68.8	75.0	80.4	136.4	97.2	85.2	76.4	70.0

After dextrin administration the blood sugar showed a similar but much greater rise by the end of the first hour. From the fasting level of 80 mg. per 100 c.c., the blood sugar rose to 136 at the end of the first hour, an increase of 70 per cent. By the end of the second hour the drop had not reached as low a level as with dextrose, the figure being 97, or 21 per cent above fasting. At the end of the third hour the blood sugar was 85, or still 6 per cent above the fasting level. The seven available observations at the end of the fourth hour gave 76.4, or a drop of 5 per cent below fasting level. The two fifth-hour observations averaged 70, or 13 per cent below fasting level.

HYPERBILIRUBINEMIA FOLLOWING ADMINISTRATION OF SULFONAMIDES*

A. Cantarow, M.D., and C. W. Wirts, M.D.†
Philadelphia, Pa.

THE present report is concerned with the occurrence of hyperbilirubinemia and other evidence of hepatic functional impairment during or after administration of sulfonamide compounds to twenty patients.

COMMENT

The pertinent data are presented in the table. Visible icterus was absent in six instances (Cases 1, 4, 12, 14, 15, 19). Total and direct-reacting bilirubin was determined by the method of Malloy and Evelyn.[1] The existence of hyperbilirubinemia was first noted one to seven days after institution of sulfonamide therapy, after administration of 6 to 24 Gm. of the drug, and with blood sulfonamide concentrations of 4 to 14 mg. per 100 c.c. Recovery occurred in every case.

It is generally stated that hepatocellular damage occurs not infrequently during administration of sulfanilamide,[2-9] seldom with sulfapyridine,[2] and rarely with sulfathiazole,[2] while it has not been observed following the use of sulfadiazine.[2, 10] In the present series, evidence of hepatic functional impairment, other than hyperbilirubinemia and excessive urobilinuria, was demonstrated in Cases 2, 6 (sulfanilamide), 10, 11, 13 (sulfathiazole), 15, 16 (sulfapyridine), 17, 18, and 20 (sulfadiazine). In Case 7 the hyperbilirubinemia was probably fundamentally of hemolytic origin, as suggested by the absence of bromsulfalein retention, the anemia, and the relatively low proportion of direct-reacting bilirubin in the serum. The same may be true of Cases 4 and 19. In Cases 1 and 2, 4 Gm. of sulfanilamide was placed in the peritoneum at the time of operation. It has been shown[6] that additional sulfonamide therapy following this procedure enhances the possibility of development of hepatitis. Because of the occasional development of hyperbilirubinemia and other evidence of hepatic functional impairment in patients with peritonitis and pneumococcus pneumonia, their occurrence in Cases 1, 3, 12, 19, and 20 cannot be attributed definitely to the effect of the sulfonamides.

CONCLUSIONS

These data indicate that hyperbilirubinemia and other evidence of hepatocellular damage may occur during the course of administration of sulfadiazine, as well as sulfathiazole, sulfapyridine, and sulfanilamide. Routine determina-

as outlined by Bliss and Marks.[6] The variance ascribable to differences in patients was about 25 per cent of the total. This points to the necessity of using a considerable number of patients and emphasizes the wisdom of having each patient serve as his own control. The "t" value of 6.305 ($P = < 0.001$) again shows that dextrins were significantly more effective in raising the blood sugar level than was dextrose.

It is impossible to state with certainty the reason for dextrin causing a higher and more prolonged rise in the blood sugar level than with dextrose itself. It is generally held that dextrins in the intestine undergo enzymic hydrolysis to maltose and then to dextrose, which is absorbed in the usual manner. The time factor of this hydrolysis may be the reason for the prolonged rise of blood dextrose after dextrin. Two other possibilities also present themselves: better absorption of the dextrose derived from dextrin, or a slower storage of the dextrose as glycogen by liver and muscle, although no evidence exists as to why such dextrose should behave different from pure dextrose. It is also recognized that the dextrins may on hydrolysis yield some slowly metabolized reducing substance which could react with the Shaffer-Somogyi reagents. No information is available on this point.

SUMMARY AND CONCLUSIONS

1. Twenty-three patients with chronic ulcerative colitis were studied as to the oral dextrose and oral dextrin tolerance tests.

2. One hour after dextrose administration the true blood dextrose had risen 42 per cent over the average fasting level while after the dextrin administration the blood dextrose had in the same time increased 70 per cent.

3. Two hours after dextrose the blood dextrose level was 7 per cent above the fasting level while the level in the dextrin group was 21 per cent above the fasting level.

4. Three hours after dextrose the blood dextrose level was 10 per cent below the fasting level while in the dextrin group it was 6 per cent above the fasting level.

5. A dextrin preparation maintained significantly higher blood dextrose levels for three hours than did dextrose in a group of patients with chronic ulcerative colitis. These findings have led to the assumption that in the patients studied dextrin was better absorbed from the intestine than was dextrose.

LABORATORY METHODS

GENERAL

A STUDY OF THE PHENOMENON OF ERYTHROCYTE SEDIMENTATION*

IV. Venous Stasis, Delay, Temperature of Sample, Containers, Agitation, and Quantity of Formed Elements as Sources of Technical Variations

Roy E. Nichols, B.V.Sc., M.Sc., Ph.D.,† Lafayette, Ind.

In PREVIOUS publications a critical survey of considerable literature,[1] choice of a reliable technique for the measurement of sedimentation,[2] and evidence substantiating my choice of the kind and quantity of anticoagulant[3] were presented. It is the purpose of this paper to discuss additional sources of technical variation and evidence of their control.

Free flow of blood without venous stasis cannot be accomplished in the horse unless a large enough needle is employed—at least a No. 10 gauge needle, or better yet, a fair-sized cannula. Repeated bleeding with a needle of this size creates considerable damage and is not advised. In lieu of the use of a large needle, a sample can be taken with a syringe (50 c.c. glass) and a smaller needle (No. 15 gauge 2 inch) in such a way that the effects of venous stasis can be avoided. Proof of this statement lies in the material which follows.

Five collecting vials, each containing the same kind and amount of anticoagulant, were filled to the 10 c.c. mark from the 15 gauge 2 inch needle inserted in the jugular vein. Venous pressure was continuous throughout the fillings and was accomplished by thumb pressure 5 to 6 inches below the needle and in degree was sufficient only to allow blood to run from the needle. Samples were allowed to settle in the vials at room temperature and then were shaken mechanically in a uniform manner. A Wintrobe tube was filled from each vial and placed in a rack to insure its perpendicularity. Results were:

Aliquot No.	M_s‡	t_{M_s}	$\angle^s M_s$
1	26 mm.	15-20 min.	30° 30′
2	20 mm.	{10-15 / 15-20} min.	37° 20′
3	18 mm.	10-15 min.	40° 20′
4	19 mm.	15-20 min.	39° 40′
5	24 mm.	15-20 min.	32° 20′

*From a thesis presented in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Graduate School of the Ohio State University, June, 1941.

†Comparative Physiologist, Department of Veterinary Science, Purdue University.

Received for publication, April 3, 1942.

‡*Definitions:*

M_s = Maximum five-minute descent in millimeters of the line of demarcation between cells and plasma.

t_{M_s} = Times in minutes between which M_s occurs. Since with the photographic apparatus one minute is the equivalent of 3 mm., this time-distance ratio is retained for the "field" technique.

$\angle M_s$ = Angle opposite the horizontal side of a right triangle having M_s as the perpendicular side and five minutes, or 15 mm., as the horizontal side.

tions of serum bilirubin concentration and tests of hepatic function would probably reveal a much higher incidence of hepatic functional impairment than has been reported heretofore following use of these agents.

Another example:

Aliquot No.	M_5	t_{M_5}	$\angle^s_{M_5}$	V%*
1	18 mm.	20-25 min.	40° 10′	39
2	18 mm.	15-20 min.	40° 10′	38.3
3	15 mm.	20-25 min.	45°	39½
4	18 mm.	20-25 min.	40° 10′	39½
5	18 mm.	15-20 min.	40° 10′	38½

This method is an improvement over continuous application of the thumb, but it still does not yield as comparable results as the technique with no stasis. In other words, if no thumb pressure is applied, except just enough to raise the vein to insert the needle, and if, after a moment's hesitation to allow free flow through the vein, a single sample is drawn into a clean dry glass syringe, and if five 10 c.c. aliquots are immediately supplied from the syringe, then results of determinations of M_5, t_{M_5}, and $\angle^s_{M_5}$ as also photographed curves of *sedimentation* from these aliquots will be comparable, for example:

Aliquot No.	M_5	t_{M_5}	$\angle^s_{M_5}$	V%
1	24 mm.	15-20 min.	32° 30′	34.5
2	23 mm.	15-20 min.	33° 30′	34.5
3	24 mm.	15-20 min.	32° 30′	35.0
4	25 mm.	15-20 min.	31° 20′	34.0
5	25 mm.	15-20 min.	31° 20′	34.5

This evidence, which may be repeated at will, is convincing enough to me that stasis of the vein at the time of withdrawal of a blood sample for the measurement of sedimentation should be avoided.

Delay.—Next let us consider the effects of delay in starting measurement following bleeding. Fig. 1, derived from three-paired samples, taken from one bleeding is typical of results. The oxalate mixture of Heller and Paul[4] was the anticoagulant used.

Ex. No.	Time after bleeding	em†	t_{em}	$\angle^s_g$
1	60 min.	28 mm.	12.8 min.	23° 00′
2	60 min.	28 mm.	11.8 min.	22° 30′
3	114 min.	30 mm.	11.8 min.	24° 40′
4	114 min.	29 mm.	11.0 min.	24° 10′
5	139 min.	20 mm.	10.3 min.	31° 30′
6	139 min.	21 min.	11.0 min.	31° 10′

1	28 mm.	10-15 min.	28° 30′	31
2	29 mm.	10-15 min.	27° 40′	32
3	28 mm.	10-15 min.	28° 30′	30.7
4	29 mm.	10-15 min.	27° 40′	31
5	19 mm.	10-15 min.	38° 50′	31
6	21 mm.	10-15 min.	36° 00′	30.7

*V% = Volume per cent of packed cells.

†em = The perpendicular distance from the estimated point of change between the vertical flexion and horizontal flexion of the photographically *recorded* sigmoid curve of sedimentation of a sample and the top line of the photograph representing 100 mm. of blood column height, i.e., estimated "fall" in millimeters at the point of change.

t_{em} = Time in minutes between the time of filling of the Wintrobe tube and the time that the point of change between the vertical flexion and horizontal flexion of the *photographically* recorded sigmoid curve of sedimentation of a sample occurs (one minute = 3 mm.).

$\angle_g$ = The least angle between the steepest slope of the sigmoid curve of sedimentation of a sample and perpendicularity.

Aliquot No.	M_5	t_{M_5}	$\angle^{s}{M_5}$
1	19 mm.	10-15 min.	39° 40′
2	21 mm.	15-20 min.	36° 00′
3	15 mm.	20-25 min.	45° 00′
4	16 mm.	10-15 min.	44° 30′
5	17 mm.	15-20 min.	41° 20′

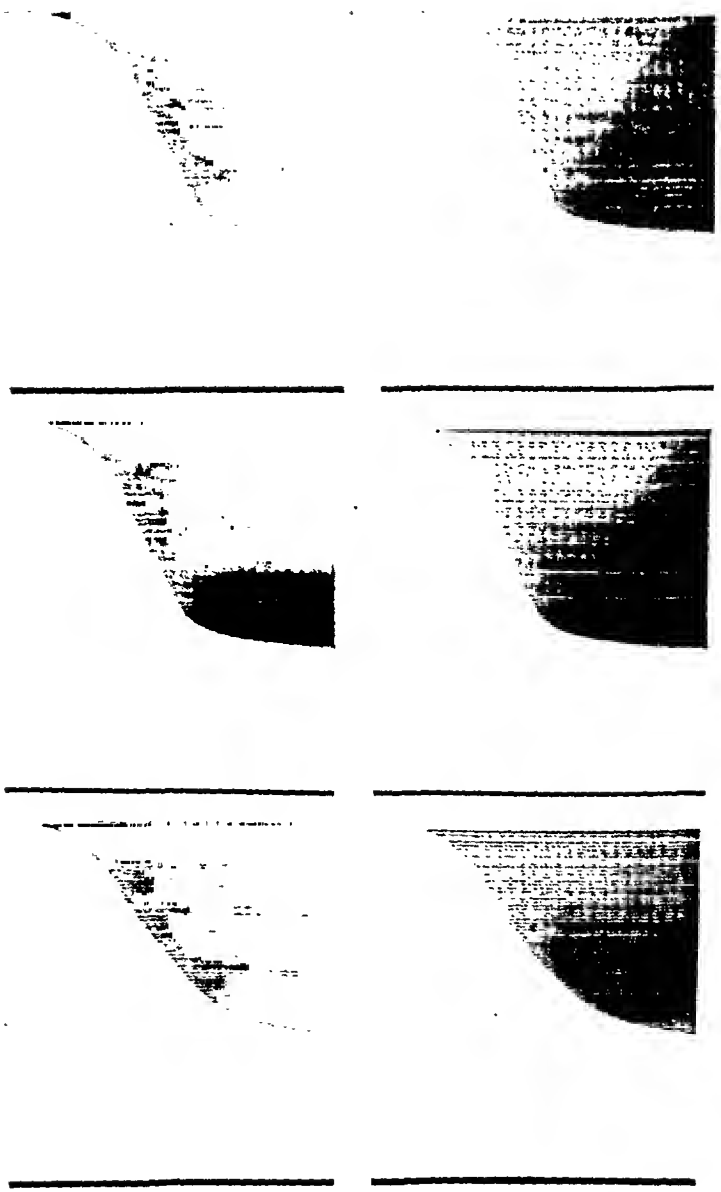

Fig. 1.

To show what happens when the thumb is removed after filling each collecting vial and is reapplied before filling the next:

Aliquot No.	M_5	t_{M_5}	$\angle^{s}{M_5}$
1	22 mm.	15-20 min.	34° 40′
2	23 mm.	15-20 min.	33° 30′
3	26 mm.	10-15 min.	30° 20′
4	22 mm.	10-15 min.	34° 40′
5	23 mm.	10-15 min.	33° 30′

With the temperatures tested the sedimentation rate increases as temperature rises. As yet no evidence has appeared to convince me that body temperature has any advantage over room temperature, or vice versa. No attempt has been made to demonstrate any mathematical relationship between temperature and sedimentation, although the possibility of such may exist.

Containers.—The reproducibility of the following tubes was tested:

Blood column—100 × 3 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$	V%
1	18 mm.	20-25 min.	40° 20′	39.3
2	18 mm.	{15-20 / 20-25} min.	40° 20′	39.3
3	18 mm.	15-20 min.	40° 20′	39.5
4	17 mm.	15-20 min.	42° 00′	39
5	18 mm.	15-20 min.	40° 20′	39

Blood column—200 × 3 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$
1	29 mm.	15-20 min.	27° 40′
2	30 mm.	15-20 min.	27° 00′
3	28 mm.	10-15 min.	28° 30′
4	28 mm.	10-15 min.	28° 30′
5	27 mm.	{10-15 / 15-20} min.	29° 20′

Blood column—100 × 6 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$
1	16 mm.	20-25 min.	43° 40′
2	16 mm.	25-30 min.	43° 40′
3	17 mm.	25-30 min.	42° 00′
4	16 mm.	20-25 min.	43° 40′
5	16 mm.	20-25 min.	43° 40′

Blood column—200 × 2 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$
1	6 mm.	30-35 min.	67° 10′
2	18 mm.	{25-30 / 30-35} min.	40° 20′
3	19 mm.	{20-25 / 25-30 / 30-35} min.	38° 50′
4	19 mm.	25-30 min.	38° 50′
5	14 mm.	30-35 min.	46° 10′

Another example of 200 × 2 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$
1	23 mm.	{10-15 / 15-20} min.	33° 40′
2	15.5 mm.	40-45 min.	44° 30′
3	24 mm.	20-25 min.	32° 30′
4	23 mm.	20-25 min.	33° 40′
5	21 mm.	20-25 min.	36° 00′

As can be seen all have fair reproducibility except the 200 × 2 mm. columns. Even with many efforts to fill uniformly these tubes, erratic results ensued. Despite these efforts I still feel that it is more reasonable to believe that variations are in a large part the result of discrepancies in tube filling and not of capillarity in a 2 mm. tube. Horse blood will not flow from an

The following is an example where potassium oxalate alone is used as an anticoagulant (Fig. 2). Approximately a ninety-minute interval exists between Example 1 and Example 2, both of which are from the same sample of blood.

Ex. No.	em	t_{em}	$\angle^s_g$
1	27 mm.	11.0 min.	26° 50′
2	8 mm.	9.5 min.	69° 20′

Ex. No.	M_5	t_{M_5}	$\angle^s_{M_5}$	V%
1	29 mm.	5-10 min.	27° 40′	40.7
2	8 mm.	5-10 min.	71° 40′	39.7

There appears to be a slowing of the rate of separation as time progresses. Examination of many samples suggests that with the ammonium and potassium oxalate mixture of Heller and Paul there may be a slight increase in rate preceding the slowing effect. However, tests run within approximately two hours yield fairly comparable results with this anticoagulant mixture. With some anticoagulants, particularly potassium oxalate, the effects of delay are apparently more pronounced and seemingly the more anticoagulant used the sooner slowing takes place.

Fig. 2.

Temperature.—Multiple determinations of rates at almost any single temperature are repeatable, but in the interest of standardization one should obviously not attempt comparison of samples at widely different temperatures. For example:

Aliquot No.	Temperature	M_5	t_{M_5}	$\angle^s_{M_5}$	V%
1	38° C.	29 mm.	10-15 min.	27° 30′	36.5
2	38° C.	30 mm.	10-15 min.	27° 00′	36.5
3	26° C.	22 mm.	10-15 min.	34° 40′	37
4	26° C.	22 mm.	15-20 min.	34° 40′	36.7
5	6° C.	3 mm.	85-100 min.	78° 20′	37 +
6	6° C.	2.5 mm.	75-80 min.	80° 10′	37.3

With the temperatures tested the sedimentation rate increases as temperature rises. As yet no evidence has appeared to convince me that body temperature has any advantage over room temperature, or vice versa. No attempt has been made to demonstrate any mathematical relationship between temperature and sedimentation, although the possibility of such may exist.

Containers.—The reproducibility of the following tubes was tested:

Blood column—100 × 3 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$	V%
1	18 mm.	20-25 min.	40° 20′	39.3
2	18 mm.	{15-20 / 20-25} min.	40° 20′	39.3
3	18 mm.	15-20 min.	40° 20′	39.5
4	17 mm.	15-20 min.	42° 00′	39
5	18 mm.	15-20 min.	40° 20′	39

Blood column—200 × 3 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$
1	29 mm.	15-20 min.	27° 40′
2	30 mm.	15-20 min.	27° 00′
3	28 mm.	10-15 min.	28° 30′
4	28 mm.	10-15 min.	28° 30′
5	27 mm.	{10-15 / 15-20} min.	29° 20′

Blood column—100 × 6 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$
1	16 mm.	20-25 min.	43° 40′
2	16 mm.	25-30 min.	43° 40′
3	17 mm.	25-30 min.	42° 00′
4	16 mm.	20-25 min.	43° 40′
5	16 mm.	20-25 min.	43° 40′

Blood column—200 × 2 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$
1	6 mm.	30-35 min.	67° 10′
2	18 mm.	{25-30 / 30-35} min.	40° 20′
3	19 mm.	{20-25 / 25-30 / 30-35} min.	38° 50′
4	19 mm.	25-30 min.	38° 50′
5	14 mm.	30-35 min.	46° 10′

Another example of 200 × 2 mm.:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$
1	23 mm.	{10-15 / 15-20} min.	33° 40′
2	15.5 mm.	40-45 min.	44° 30′
3	24 mm.	20-25 min.	32° 30′
4	23 mm.	20-25 min.	33° 40′
5	21 mm.	20-25 min.	36° 00′

As can be seen all have fair reproducibility except the 200 × 2 mm. columns. Even with many efforts to fill uniformly these tubes, erratic results ensued. Despite these efforts I still feel that it is more reasonable to believe that variations are in a large part the result of discrepancies in tube filling and not of capillarity in a 2 mm. tube. Horse blood will not flow from an

inverted 3 mm. tube and seldom from a 6 mm. tube, yet with these bores replication is possible. Why the difference? Of course, with the 200 mm. tubes longer needles had to be employed for filling. Since these needles are No. 16 gauge and their outer diameter is 1½ mm., they nearly occlude the 2 mm. bore. In the necessary manipulation of the filling of the tube with a needle of this size, in all probability disturbance to the blood is greater in some fillings than in others, resulting in more complete breaking up of clumps of cells. Since the same needles can be used for filling larger bore tubes and replicate results ensue, it is thought that they are not in fault. Smaller bore needles, though they too offer disadvantages from an agitation standpoint, will have to be tried.

Next a comparison of 100 × 3 mm. and 200 × 3 mm. columns was made on aliquots of the same sample of blood. All tubes were filled with No. 16 gauge 11 inch needles:

Blood column—100 × 3 mm.:

Aliquot No.	M_5	$^{t}M_5$	$\angle^{s}M_5$
1	16 mm.	20-25 min.	43° 40′
2	15 mm.	20-25 min.	45° 00′
3	17 mm.	25-30 min.	42° 00′

Blood column—200 × 3 mm.:

Aliquot No.	M_5	$^{t}M_5$	$\angle^{s}M_5$
4	20 mm.	20-25 25-30 min.	37° 30′
5	22 mm.	20-25 min.	34° 50′
6	21 mm.	20-25 min.	36° 10′

Four 200 × 3 mm. tubes were filled to different levels:

Aliquot No.	Column height	M_5	$^{t}M_5$	$\angle^{s}M_5$	$\%M_5$*	$\angle^{s}\%M_5$
1	200 mm.	22.5 mm.	20-25 min.	34° 00′	11.25 mm.	52° 20′
2	150 mm.	18.5 mm.	10-15 min.	39° 30′	12.3 mm.	49° 50′
3	100 mm.	24 mm.	10-15 min.	32° 30′	24 mm.	32° 30′
4	50 mm.	13 mm.	5-10 min.	48° 30′	26 mm.	30° 20′

As can be seen by examination of these trends the actual maximum five-minute drop in the line of demarcation between cells and plasma is greater in 200 mm. columns than in 100 mm. Results in tubes of like bore filled to four different levels suggest that M_5 may be less and less as the height of the column is decreased.

If, however, one were to reduce the actually obtained values of M_5 to a percentage basis, then values of $\%M_5$ are not equal but increase as the column height decreases—additional indication that there is not a simple arithmetical relationship between column height and maximum drop. Attempts to demonstrate some other type of mathematical relationship will have to be left for future work—such a relationship theoretically might exist.

For an example of comparison of like columns of different diameter:

Blood column—100 × 3 mm.:

Aliquot No.	M_5	$^{t}M_5$	$\angle^{s}M_5$
1	15 mm.	25-30 min.	45° 00′
2	15 mm.	20-25 min.	45° 00′
3	17 mm.	20-25 min.	42° 00′

*% M_5 equals M_5 reduced to a percentage basis.

Blood column—100 × 6 mm.:

4	16.5 mm.	20-25 min.	42° 50′
5	16.5 mm.	20-25 min.	42° 50′
6	17 mm.	20-25 min.	42° 00′

Results are close.

As examples of the effects of deviations from perpendicularity:

Aliquot No.	Angles	M_5	$^tM_5$	$\angle^s M_5$	V%
1	90°	24 mm.	10-15 min.	32° 30′	34.7
2	80°	31 mm.	5-10 min.	26°	34.3
1	90°	21 mm.	15-20 min.	36° 10′	38.00′
2	80°	28 mm.	10-15 min.	28° 30′	38.00′

Five-minute readings for the angulated tubes were read directly from the graduations of the tubes. Little calculation is necessary to show that despite this, values of M_5 are greater than those of the corresponding perpendicular tubes.

To summarize, longer columns yield greater actual values of M_5. M_5 is not directly proportional to column height, for when values of M_5 are reduced to percentage drops, these are greater in shorter columns. There is apparently no significant difference between columns of 3 mm. diameter and columns of 6 mm. diameter. Two millimeter columns should be avoided. Small deviations from perpendicularity are apparently sources of discrepancy.

Shaking.—As one may have noticed in the review of literature on agitation prior to starting measurement of sedimentation,[1] too little stress has been placed upon the necessity of uniform dispersion of elements before measurement is begun. It was first reasoned that, if multiple aliquots from the same sample of blood were shaken to a point where they would yield fairly close values of volume per cent, their sedimentation rates should agree. The fallacy of such reasoning was soon clearly demonstrated. Such reasoning would apply to a simple sedimenting system where the dispersed elements remain discrete, but not to blood in which the phenomena of rouleaux formation and agglutination take place, and more especially not to blood in which this aggregating tendency is very pronounced, as is the case with horse blood. It has been reported that no aggregation occurs intravascularly in healthy human beings but such has not been reported in healthy horses. In fact, Fahraeus[5] states that close examination of the finer vessels of the mesentery of the horse reveals that the corpuscles are so strongly aggregated that they do not separate during flowing. No suspension exists. The erythrocytes flow as a compact stream in the middle of the vessel, and only when the stream is slowed by pressure on the supplying arteries does this string show granulated outlines and finally break to pieces. Whether Fahraeus' observation can be classed as evidence that a certain degree of aggregation occurs intravascularly in the healthy horse is certainly debatable. The very removal of mesentery from the abdominal cavity for examination may have in itself caused a certain degree of slowing in the vessels, this favoring rouleaux formation. More especially might this be true since the aggregating tendency is naturally very great in horse blood.

The problem of obtaining a uniform suspension of elements, whether singular, rouleaux, or aggregates of rouleaux, has been indeed a difficult one. Naturally, the first method attempted consisted of filling tubes as soon as possible

after bleeding, the aliquots being agitated by hand until the samples for filling the Wintrobe tubes were drawn. Such yielded erratic results.

The next method tried consisted of allowing the collecting vials to set until separation was fairly complete, usually ten to twenty-five minutes, and then shaking them as uniformly as possible by hand. This method was not dependable.

Aliquot No.	M_s	${}^tM_s$	$\angle^s M_s$	V%
1	21 mm.	15-20 min.	36° 00′	35−
2	24 mm.	15-20 min.	32° 30′	35+
3	23.5 mm.	15-20 min.	33° 00′	35

Striking the collecting vial upon a rigid surface only created more incomparable results:

Aliquot No.	M_s	${}^tM_s$	$\angle^s M_s$	V%
1	20.5 mm.	10-15 min.	36° 40′	35
2	21 mm.	5-10 min.	36° 00′	35+
3	15 mm.	10-15 min.	45° 00′	35

In face of erratic results with manual agitation, mechanical means were attempted. Several styles of mechanical agitators were constructed and tried. Finally, one was built[2] with a vial holder suspended from four 7¾ inch spring steel arms. This was driven in such a way as to yield a ¾ inch path of motion over an arc of 7¾ inch radius, yet, since four arms were used, the vial remained in a perpendicular position. The fact that the ends of the stroke were slightly higher than the center of the arc is thought to be an added assistance in overcoming the effects of the force of gravity (which theoretically is ever present and must be counteracted before dispersion can take place). When the path of the arc was more shallow (12 inch radius), layering effects were frequently encountered. At present the speed is 564 strokes per minute. It is felt that since fairly comparable results can usually be obtained when tubes are filled from different heights of replicate aliquots of the same sample of blood, in all probability this agitator is at least practically sufficient.

Aliquot No.	Height	M_s	${}^tM_s$	$\angle^s M_s$	V%
1	¾	19 mm.	20-25 min.	38° 50′	41.7
2	½	18 mm.	20-25 min.	40° 20′	42
3	¼	17 mm.	20-25 min.	42° 00′	41.7
4	0	19 mm.	20-25 min.	38° 50′	42

Additional evidence of its efficiency is noted when five Wintrobe tubes are filled from the bottom of the same 10 c.c. sample:

Tube No.	Height	M_s	${}^tM_s$	$\angle^s M_s$	V%
1	0	16 mm.	20-25 min.	43° 40′	38
2	0	16 mm.	20-25 min.	43° 40′	38
3	0	16 mm.	15-20 min.	43° 40′	38.3
4	0	17 mm.	15-20 min.	42° 00′	38+
5	0	16 mm.	15-20 min.	43° 40′	38+

The foregoing examples were from samples which were allowed to settle; each sample was shaken for fifteen minutes by placing the collecting vials into the shaker one minute apart and filling the tubes one minute apart.

The first attempts at arriving at a safe time of mechanical agitation for samples immediately placed in the shaker yielded results shown in Fig. 3. Data from these examples:

Ex. No.	Time shook	em	t_{em}	$\angle^s_g$
1	2 min.	31 mm.	10.5 min.	22° 10′
2	3 min.	29 mm.	9.3 min.	20° 00′
3	3.5 min.	29 mm.	8.3 min.	17° 50′
4	4.5 min.	26 mm.	7 min.	21° 30′
5	5.5 min.	23 mm.	7 min.	17° 30′

Ex. No.	M_s	t_{M_s}	$\angle^s M_s$	V%
1	27 mm.	5-10 min.	29° 20′	31.8
2	29 mm.	5-10 min.	27° 20′	31.8
3	33 mm.	5-10 min.	24° 40′	31
4	35 mm.	5-10 min.	23° 20′	31
5	39 mm.	5-10 min.	21° 10′	31.3

As can be seen, five and one-half minutes at a speed of about 600 strokes per minute was apparently not sufficient to reduce aggregated elements to at least minimum size.

To determine whether results might be comparable if samples were drawn, immediately placed in the shaker, and agitated for fifteen minutes:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$	V%
1	17 mm.	25-30 min.	42° 00′	44
2	16 mm.	20-25 min.	43° 40′	43.5
3	13 mm.	20-25 min.	48° 20′	44
4	20 mm.	25-30 min.	37° 20′	44
5	20 mm.	25-30 min.	37° 20′	43.5

Results were still too variable.

If samples were immediately placed in the shaker and agitated for forty minutes:

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$	V%
1	23.5 mm.	10-15 min.	33° 00′	37−
2	23.5 mm.	10-15 min.	33° 00′	36.3
3	22 mm.	15-20 min.	34° 40′	36.7
4	23.5 mm.	10-15 min.	33° 00′	36.5
5	23.5 mm.	10-15 min.	33° 00′	36+

Results agree very well.

Apparently a certain amount of aggregation takes place even during shaking, and apparently a certain amount of time following bleeding must pass before agreeable replicate values can be obtained. From a practical standpoint, if equally as good results can be obtained by allowing the blood to separate before agitation as by prolonged agitation, the logical choice is to allow settling to take place first. There is additional experience in favor of this choice. In samples of very slow blood, agitation, if commenced immediately after bleeding, must be continued longer than in samples from fast blood. In slow blood one is always reasonably doubtful about reaching that phase of agitation where replication is possible. Where slow blood is allowed to settle first, in no case so far has there been evidence to suggest that agitation for fifteen minutes was insufficient.

It was first thought that if blood was allowed to separate first, speed alone might bring about uniformity of suspension. Blood was allowed to settle and

then was placed in the agitator between 500 and 600 strokes per minute for varying times. There was no visible hemolysis at this speed while at faster speeds there was occasional hemolysis in some pathologic cases.

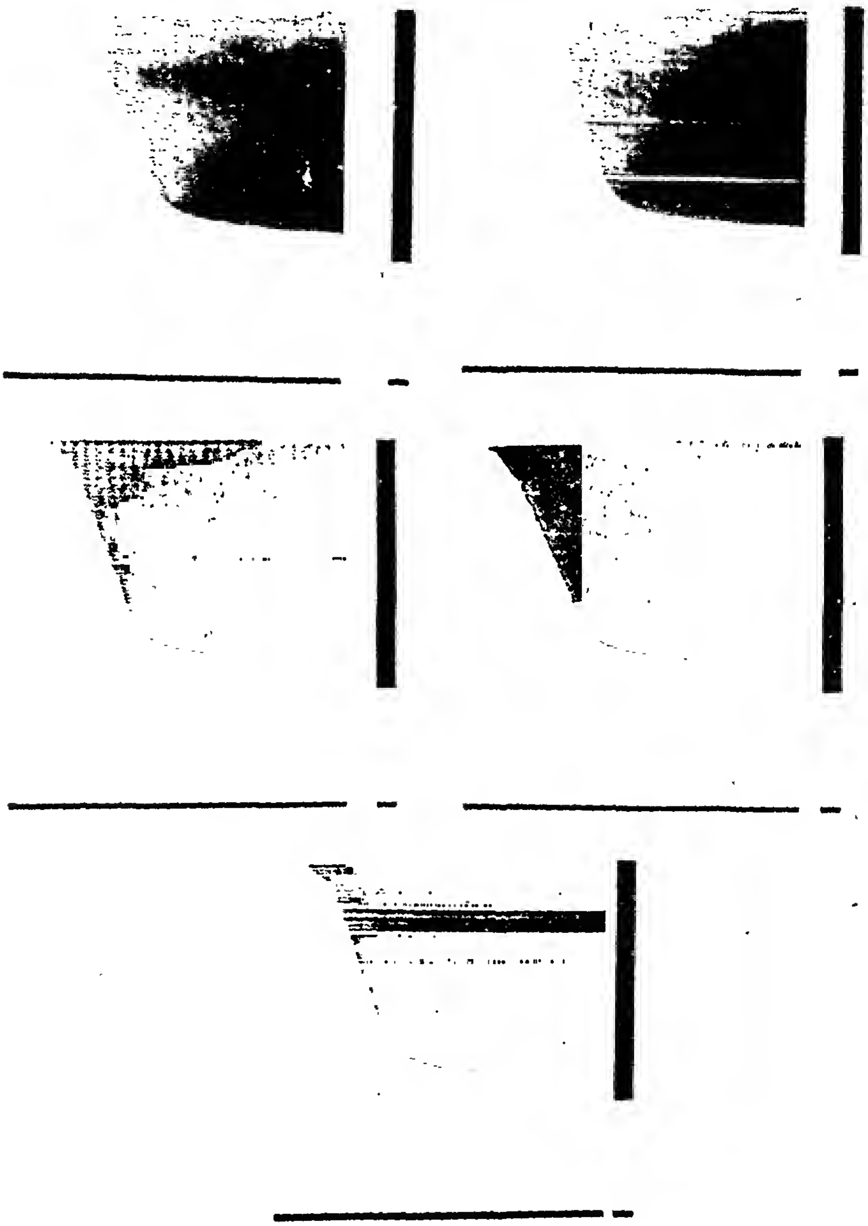

Fig. 3.

Results were similar to:

Aliquot No.	Time Shaken	M_5	${}^{t}M_5$	$\angle^{s}M_5$	V%
1	1 min.	12 mm.	15-20 min.	50° 30′	42½
2	5 min.	16 mm.	30-35 min.	43° 40′	43–
3	10 min.	18 mm.	20-25 min.	42° 40′	42–
4	15 min.	19 mm.	20-25 min.	38° 40′	42½

Shaking for thirty minutes after the samples have been allowed to separate yields no more comparable figures than shaking for fifteen minutes. In more rapid samples shaking for five minutes will yield comparable values, but I have greater confidence in fifteen minutes as a routine shaking time.

It was earlier mentioned[2] that variations in t_{em} and the limits of t_{M_5} were encountered even when values of em and M_5 were not far off. Volume percentages were within narrow limits, t_o-t_o* was carefully established, and all calculations and measurements were checked. At first it was thought that the mechanical agitation was at fault. Since at no time has it been possible to demonstrate microscopically that settled blood can be separated by agitation to a state of single cells—because rouleaux formation is so rapid in the equine species that shed blood no matter how quickly examined after bleeding cannot be found without agglutination—no definite proof of the efficacy of any type of agitation has been possible as yet. Means other than the microscope will have to be used.

However, since with some methods of filling the measuring tubes very close results were obtained while with others results were not so close, it was reasoned that in all probability the mechanical agitation merely reduced the solid elements to a certain degree of dispersion but not to the discrete state and that methods of filling measuring tubes were at fault. The early practice of removing the collecting vial from the shaker before withdrawal of blood for filling the measuring tube was stopped, and in its place was substituted the practice of withdrawing blood from the vial while the shaker was in motion, this being possible because of the short stroke of the apparatus. In addition to this, syringes attached to blunt No. 18 gauge 4½ inch needles were used in place of the earlier used glass pipettes furnished with the Wintrobe tubes, the latter being very subject to breakage when inserted into the moving vial. Results were no better.

Next it was reasoned that the suction of drawing the blood into a syringe (used earlier in the course of this problem) and the pressure necessary for its expulsion into a tube were probably in reality means of agitation in themselves; and if no uniformity existed in this practice, they might be responsible for some of the discrepancies observed. It was further reasoned that if this source of possible variation could be minimized, closer results would ensue. Since the hubs of these long-filling needles were round and fairly large, the rubber bulbs which are furnished with the Wintrobe filling pipettes were attached and tried. Before trial these bulbs were selected as to volume and degree of firmness, and only those which were comparable were employed. By using this equipment and placing more stress on forming a uniform "habit" of filling tubes, closer results of em, t_{em}, M_5 and t_{M_5} were obtained.

The problem of t_{M_5} has, however, not yet been completely solved, but a little reasoning reveals that since limits of t_{M_5} never pass beyond the next five-minute brackets and since, even if the limits of t_{M_5} are within different brackets, in practice em, t_{em}, $\angle^s{}_g$, M_5 and $\angle^s{}_{M_5}$ may be very close, this discrepancy is not too serious. After all t_{M_5} merely is a wide range within which t_{em} lies. Usually

*Time of filling the tube.

if t_{em} is close to one or the other of the limits of t_{M_5} in results where there is variation in t_{M_5}, it will be in the direction of t_{em}. Also where two readings of M_5 are close, t_{em} usually lies nearer the middle of these five-minute limits. In cases where M_5 lies between both five-minute limits, as it frequently does, t_{em} in most cases lies closer to the center five minute time. Since in practice t_{em} is usually not affected more than one minute, and rarely two minutes or more, and since in all probability $\angle^{s}{}_{g}$ in the photographic technique and $\angle^{s}{}_{M_5}$ in the "field" technique are better estimates of the speed of settling than values of either I_{em}* or I_{M_5}†, this deviation in t_{M_5} is thought not serious. Also since, if t_{em} happens to be close to one or the other of the limits of t_{M_5}, small variations in t_{em} may be sufficient to change the limits of t_{M_5}, in replicate sampling variations in values of t_{M_5}, apparently due to discrepancies in filling the measuring tubes, are not considered of distracting value.

Since replicate results agree very closely with the previously described technique of agitation and tube filling, this method is thought to be fairly dependable.

Volume Per Cent and Sedimentation.—Now comes a phase of this work which is indeed interesting and which I feel cannot be answered in a thesis purely on technique, but it might be in a problem of "apparently normal ranges." What is the relationship between the quantity of formed material and the rate at which this material separates out? Since it is quite universally recognized that the cells do not settle discretely, what effect does the quantity of formed elements have upon rouleaux formation and agglutination?

Rouleaux formation has been said to be merely a type of agglutination in which the cells, because of their specific shape, take on a nummular appearance, other physical factors apparently being similar. Is such unreasonable? Rouleaux, as observed microscopically, are said to attain a certain average length and from thence on agglutination is of rouleaux and not single cells. It has even been suggested[5] that agglutination continues until the whole mass of cells seems to form a spongelike architecture.

It has also been suggested by Balachowsky[6] that:

1. Red blood cells forming rouleaux and conglomerates constitute a network which is the skeleton of the blood.

2. Under the influences of weight and through a series of local depressions there occurs a general heaping of the blood skeleton on the bottom of the receptacle.

3. This blood skeleton is not deprived of solidarity for (a) the configuration of a given portion may remain unchanged for a long period of time. (b) The free upper border of the bulk of the erythrocytes preserves its shape for a long period. (c) There exists a force of resistance against the collapse of the blood skeleton other than viscosity.

4. The solidarity of the blood skeleton, being a function of the tonus of its constituents, is a new factor denominated "hematonia."

---

*I_{em} = An index $\frac{cm}{t_{em} \times 3}$.

†I_{M_5} = An index calculated by dividing the "falls" in millimeters between which M_5 occurs by their corresponding times $\times$ 3 (3 mm. = one minute).

Balachowsky feels that sedimentation of erythrocytes is not, as has been assumed, merely a simple phenomenon of sedimentation, but a more complicated reaction in which the effects of heaping play an important part. For this reason, he would dominate the phenomenon as the sedicompilation of erythrocytes.

If one closely watches a Wintrobe tube of horse blood, he can observe that the edges of the column of blood present a certain, ragged appearance, sometimes even before much settling has taken place. Is it unreasonable to assume that this is part of the agglutination phenomenon and that this effect may be general throughout the column? Another common place that this may be observed is in the pipette of a Dare hemoglobinometer. The layer of blood is sufficiently thin for one to watch the gradual agglomeration and settling.

Of course, one can observe a certain limitation to the size of rouleaux and clumps under a cover slip. The physical boundary of the blood column in one direction (height) is a matter of microns, and this in itself physically limits, to some extent at least, the degree of agglomeration. The dilution necessary to demonstrate rouleaux probably is in itself a limiting factor. However, cover-slip specimens of a sample of blood may show a certain limit to agglomerate size while tubes of the same sample may present evidence of mass agglomeration. In other words, in samples examined under a cover slip, mass agglomeration is quite free in two dimensions, but somewhat limited in the third, while in tubes, agglomeration is practically unlimited in three dimensions, at least before mass collapse.

Should it be said that the descent of the line of demarcation between cells and plasma represents a measure of size of agglutinates, or should it be said that the fall of this line of demarcation represents a measure of mass agglutination and mass collapse?

As to the effect of the quantity of formed material, cannot one say that, being one of the factors controlling the degree of agglutination as observed microscopically, it probably is one of the controlling factors of the degree of mass agglutination? Examinations of cover-slip preparations of various dilutions of cells and maximum five-minute falls on the same sample seem to substantiate this, as for example:

	V%	M_5	$^tM_5$	$\angle^s M_5$
Original sample:	43	21.9 mm.	10-15 min.	34° 40′
Volume altered to:	48	14 mm.	10-15 min.	46° 10′
"	39	25 mm.	5-10 min.	31° 30′
"	29.5	48 mm.	0-5 min.	17° 30′
"	20	61 mm.	0-5 min.	13° 50′
"	10.5	72 mm.	0-5 min.	11° 50′

Since the degree of agglutination was too great to count rouleaux and estimate the number of cells per rouleaux, the blood of the same animal was diluted (with 0.9 per cent sodium chloride) so that such might be accomplished. As expected, the size and number of agglomerates diminished with dilution, next the size and number of rouleaux diminished, until finally all single cells existed. Since the border of cells and plasma became more and more hazy the greater the dilution, actual estimations of M_5 were given up.

In dilutions showing hazy plasma, it will be noticed that that portion of the elements which does settle out rapidly gradually diminishes in volume as dilution increases, until finally the suspension comes apparently to its maximum stability. *This "titer" corresponds roughly at least to the point at* which only single cells are observed in the cover-slip preparations.

As purely a general observation there seems to be a concentration of elements in apparently healthy blood where the point of change in the sigmoid curve roughly numerically equals the percentage volume of elements, namely, at about 33⅓ per cent or ⅓, of the column height. The point of change in "normal" samples is seemingly less than 33⅓ mm. when the volume per cent is greater than 33⅓, and vice versa. Proof of this observation has not been attempted in this problem nor has any attempt been made to relate mathematically the point of change of curves of sedimentation with volume percentages because it is thought that such must entail examination of many "normal" samples and their adjustment to various concentrations—a task which would in itself entail more time and effort than can be afforded this thesis and could well be included in a study of normals. Nevertheless, Fahraeus[5] must have been thinking of a somewhat similar observation when he made this statement: "In general the sinking velocity of the upper corpuscle layer is diminished when it has sunk ⅓rd of the height of the blood column, i.e., in the tubes used by me (150 mms.) when the line of demarcation has descended 50 mms."

To theorize, if a mathematical relationship can be proved to exist between the point of change of the sigmoid curve representing the descent of the line of demarcation between cells and plasma and the percentage volume of formed elements, then with this knowledge, if the point of change is not as expected for a particular percentage, its deviation from the expected might reflect alterations produced by factors other than the volume percentage of elements. Such alterations might be estimated without standardization of the quantity of formed elements for the particular sample. Such no doubt would be an advantage.

To summarize in a general way, we seem to have least settling at dilutions where cells are discrete: a gradual increase in settling of at least a portion of the cells (probably as rouleaux or small clumps) as dilution becomes less; a point where maximum speed of separation seems to occur: then a gradual decrease in separation speed (as determined by the descent of the line of demarcation between cells and plasma) as concentration increases, there possibly being a mathematical relation between the slowing of the speed of separation and the increase in concentration.

BLOOD CLOT RETRACTION*

I. Measurement of the Extracorpuscular Volume of the Clot

P. M. Aggeler, M.D., and S. P. Lucia, M.D., San Francisco, Calif., and
L. M. Hamlin, M.A., Berkeley, Calif.

Direct observation of the blood clot may reveal gross evidences of friability and deficient retraction. However, quantitative measurements are required to compare retraction of the blood clot of different patients, or of that of the same patient over a period of time. A method for estimating the degree of clot retraction, called the "serum volume index," was introduced by Boyce and McFetridge.[1] A quantity of blood, preferably 3 c.c., was collected in a graduated centrifuge tube and allowed to stand at room temperature. At the end of four hours the total volume of the specimen was noted, the clot was removed, and the residual volume of serum was recorded. In normal subjects the volume of serum was stated to be equivalent to 50 per cent of the volume of the specimen. There was a marked diminution of the serum volume in some jaundiced patients who suffered from abnormal bleeding. The authors expressed the deficiency of clot retraction in terms of the "serum volume index," which was obtained by dividing the volume of the serum by one-half of the total volume of the blood specimen. The index for normal subjects was 1.00, and values less than one were considered as indicative of a tendency to bleed. It was observed that if anemia were present, the serum volume would normally be greater than half the blood volume, and a correction based on the erythrocyte count was made in calculating the index.[2] It appears to us that in addition the mean volume of the red blood corpuscles and increases in the number of leucocytes may influence the results of the test. Nevertheless, the serum volume index is a valuable bedside test for the detection of deficient clot retraction.

Macfarlane[3] introduced a new method for measuring clot retraction which makes use of a graduated centrifuge tube into which is fitted a cork bored to receive a glass rod. The glass rod measures about 0.5 inch shorter than the tube and has a small expansion about 0.5 inch from the lower end. To perform the test, 5 c.c. of blood obtained by venipuncture are immediately introduced into the tube, the glass rod and cork are fitted, and the tube is placed in a water bath at 37° C. One hour after a firm clot has formed, the tube is removed from the bath, the clot is carefully freed and removed on the glass rod. The volume of serum is measured directly, and retraction is expressed in terms

Aided by a grant from Mr. Frank Kennedy and from the Christine Breon Fund.
Received for publication, April 27, 1942.

of the percentage of the serum volume. The author found that the normal serum volume per cent fluctuated between 43.9 and 65.5 per cent. No correction was made for anemia.

The "clot retraction index" introduced by Mettier and Witts in 1939[3] is performed in a manner similar to that described by Macfarlane, except that a correction for anemia is made. The packed cell volume is added to the serum volume per cent and the sum is divided by two. In normal subjects the "clot retraction index" varies from 38 to 60. We have found the "clot retraction index" to be a useful clinical test.[6, 7]

In the course of a study of the various factors influencing the volume of the clot, we have found it convenient to express the character of the clot in terms of the extracorpuscular volume of the clot, which may be defined as the difference between the volume of the clot and the volume of the cells contained therein. It is our purpose to record the results of observations made in normal subjects and in patients suffering from abnormal bleeding.

METHOD

Slight modifications of Macfarlane's method for examining the clot were made. The upper end of a copper wire about 1 mm. in diameter is attached to a cork. The free end of the wire is bent in the shape of a hook. An arbitrary amount of venous blood, usually 5 c.c., is carefully transferred to a graduated centrifuge tube, and the cork and wire are fitted so that the hook is immersed in the upper layers of the specimen. After coagulation of the blood has occurred, the tube is placed in a water bath (37° C.) for one hour. It is then taken from the bath, the total volume of the specimen is recorded. the clot is elevated, allowed to drain and then removed. The residual volume of serum is measured, and when it is subtracted from the total volume of the specimen, the clot volume remains. To obtain the volume per cent of the blood clot, the observed volume of the clot is divided by the total volume of the specimen, and the quotient is multiplied by 100. (The measurement of the packed cell volume, including all cellular elements, is obtained by centrifugalization of a separate specimen of oxalated blood at 3,000 r.p.m. for thirty minutes.) The difference between the packed cell volume in per cent and the clot volume in per cent is the per cent of the total blood specimen occupied by the extracorpuscular volume of the clot. A value of zero implies that the clot is composed entirely of cells, and hence that excellent retraction has occurred. A high figure indicates that a large amount of extracorpuscular fluid is retained in the clot and that retraction is deficient. Occasionally, the clot volume is slightly smaller than the packed cell volume. This apparent discrepancy could be due to the inherent errors of the method, or it may be that fluid has been expressed from the cells, or that the spatial relationships of the cells are different when they are packed by centrifugal force in contrast to the agglomerations brought about by the natural retraction of the blood clot. Whatever the cause of this phenomenon, it always indicates excellent clot retraction.

Errors of the Method.—The inherent error of the method when tested by serial examination is approximately 5 per cent. The presence of the wire within the clot introduces a constant error of less than 0.5 per cent, which for con-

venience is neglected in the calculations. Occasionally, some of the cells may escape from the clot and settle at the bottom of the tube. This is frequently seen in specimens obtained from patients suffering from thrombocytopenia, polycythemia vera, and congenital hemolytic icterus. In these instances the serum is centrifugalized and the volume of the clot is corrected by adding to it the volume occupied by the escaped cells. The extracorpuscular volume of such clots will be less by an amount equal to the fluid which would be characteristically occluded in such clots had these cells remained within the clot. Such errors are slight and do not alter the trend of the results.

In all experiments the platelet counts were done on capillary blood after the method of Rees and Ecker, and the prothrombin concentration after the method of Quick.

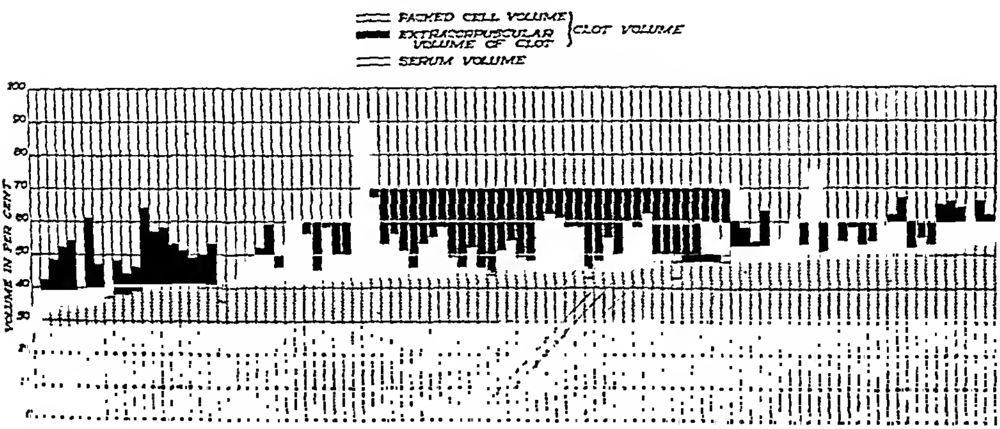

Fig. 1.—Relation between serum volume, packed cell volume, clot volume, and extracorpuscular volume of the clot in 100 normal subjects.

Material of the Study.—Specimens of blood from the following groups of persons were examined:

1. One hundred normal persons in whom the platelet counts were within normal limits (250,000 to 600,000) and in whom the prothrombin concentration was 70 per cent or greater.

2. Forty-two patients suffering from hypoprothrombinemia in whom the platelet counts were greater than 200,000 per cubic millimeter and in whom the prothrombin concentration was 50 per cent or less.

3. Thirty-five patients suffering from thrombocytopenia in whom the platelet count was 200,000 per cubic millimeter or less and in whom the prothrombin concentration was greater than 50 per cent.

RESULTS

The serum volume, clot volume, packed cell volume, and extracorpuscular clot volume expressed in per cent for each of 100 normal subjects are given in Fig. 1. The data for those with hypoprothrombinemia are given in Fig. 2, and for those with thrombocytopenia in Fig. 3. There did not appear to be any significant relationship between the packed cell volume and the extracorpuscular volume of the clot in any of these patients. In Fig. 4 the frequency distribution of the values for the extracorpuscular volume of the clot observed in each

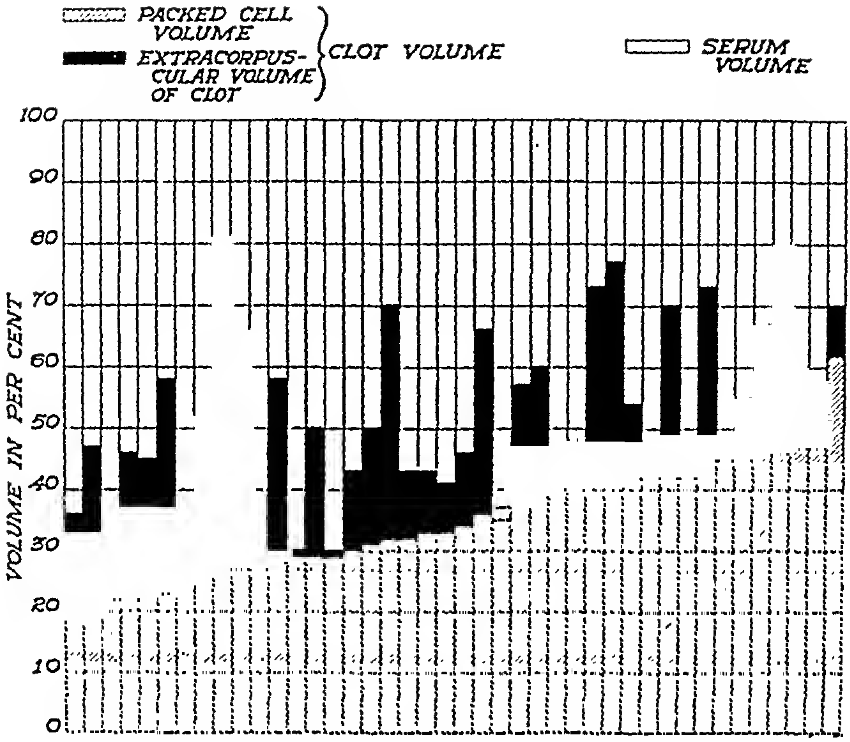

Fig. 2.—Relation between serum volume, packed cell volume, clot volume, and extracorpuscular volume of the clot in 42 subjects with hypoprothrombinemia.

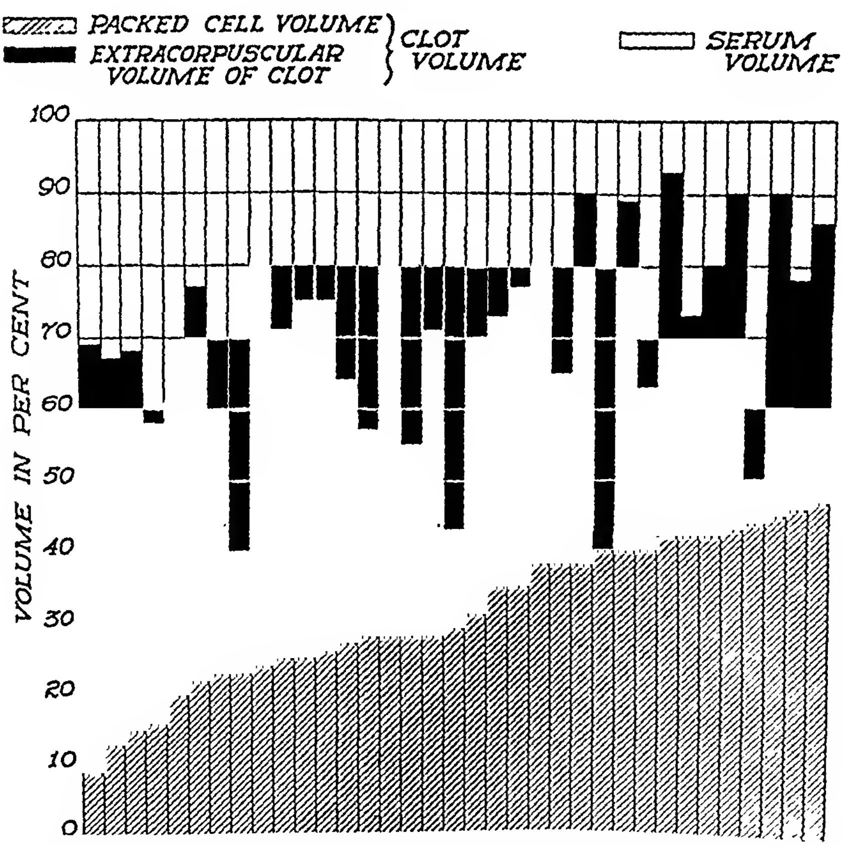

Fig. 3.—Relation between serum volume, packed cell volume, clot volume, and extracorpuscular volume of the clot in 35 subjects with thrombocytopenia.

of the three groups is given. It can readily be seen that the values for the extracorpuscular volume of the clot of many patients with hypoprothrombinemia overlap the normal range, while the values for most of the patients with thrombocytopenia fall outside the normal range. The results of the statistical analysis of these data are given in Table I. The standard statistical method was used in setting up the limits of normality. The limits of significance of the data were arbitrarily set at two standard deviations from the mean, which includes approximately 96 per cent of the observations. The mean is taken at the point of reference. All measures calculated were at least three times their sampling errors. The mean value of the extracorpuscular volume of the clot for the normal group was 9.1 per cent, the range of the values being − 5.9 to 24.1 per cent. The extracorpuscular volume of the clot was greater than 24.1 per cent in 13 of 42 patients with hypoprothrombinemia and in 30 of 35 patients with thrombocytopenia. The respective mean values for these groups were 18.2 and 38.9 per cent.

TABLE I

POINT AND RANGE MEASURES OF THE EXTRACORPUSCULAR VOLUME PER CENT OF THE BLOOD CLOT*

	MEAN	σ_x	M ± 1σ_x	M ± 2σ_x	MEDIAN (FROM OGIVE)
Normals (N=100)	9.1	7.5	1.6 − 16.6	(−) 5.9 − 24.1	8.7
Hypoprothrombinemia (N=42)	18.2	12.4	5.8 − 30.6	(−) 6.6 − 43.0	15.0
Thrombocytopenia (N=35)	38.9	14.1	24.8 − 53.0	10.7 − 67.1	42.3

*Using three sampling errors as a criterion, all measures are statistically significant.

A further study of the structure of normal and abnormal blood clots was made by histologic examination after fixation in 10 per cent formalin in absolute alcohol. In the normal clot (Fig. 5) the erythrocytes are densely packed. A poorly retracting clot from a patient suffering from thrombocytopenia is demonstrated in Fig. 6, which shows loose packing of the erythrocytes, uniform fragmentation of the clot, and irregular inclusion of large pools of serum.

The extracorpuscular volume of the clot is composed of fibrin and unexpressed serum. Experimentally, we have determined that the volume occupied by fibrin in the normal recalcified plasma is equal to approximately 1 per cent of the total specimen.

DISCUSSION

Macfarlane suggested a relationship between a decrease in packed cell volume and a reduction in the volume of the clot when retraction is normal. However, he states: "This relationship does not apply when, in abnormal cases, retraction is deficient. In such cases retraction may be brought to a standstill not by the volume of the cells contained within the clot, but by an inherent inability of the fibrin to contract to the extent normally attained. Under these conditions it is clear that a reduction in the cell volume cannot increase the extent of retraction.

"Thus, whereas it is possible to correct by a simple calculation for the effect of anemia if retractility is normal, no such correction can be applied if it is

deficient. Hence the application of a correction to pathological cases will produce distortion, since deficient retraction will be revealed in anemic cases more often than in those with a normal cell volume."

It appears to us that blood clot retraction may be controlled through an equilibrium existing between the retractile force of the fibrin on the one hand, and the opposing resistance to aggregation of the retained cells on the other. Their relative influence may vary considerably, depending upon many factors, including the volume of the packed cells and the quantity and quality of the platelets, prothrombin, and fibrin. In the blood of normal subjects conditions appear to be fairly well balanced so that the average extracorpuscular volume of the clot is approximately 10 per cent of the original specimen. In the abnormal subject the same forces operate, but the balance may be upset because the retractile power of the fibrin may be diminished, and equilibrium is established when the average extracorpuscular volume of the clot is relatively large.

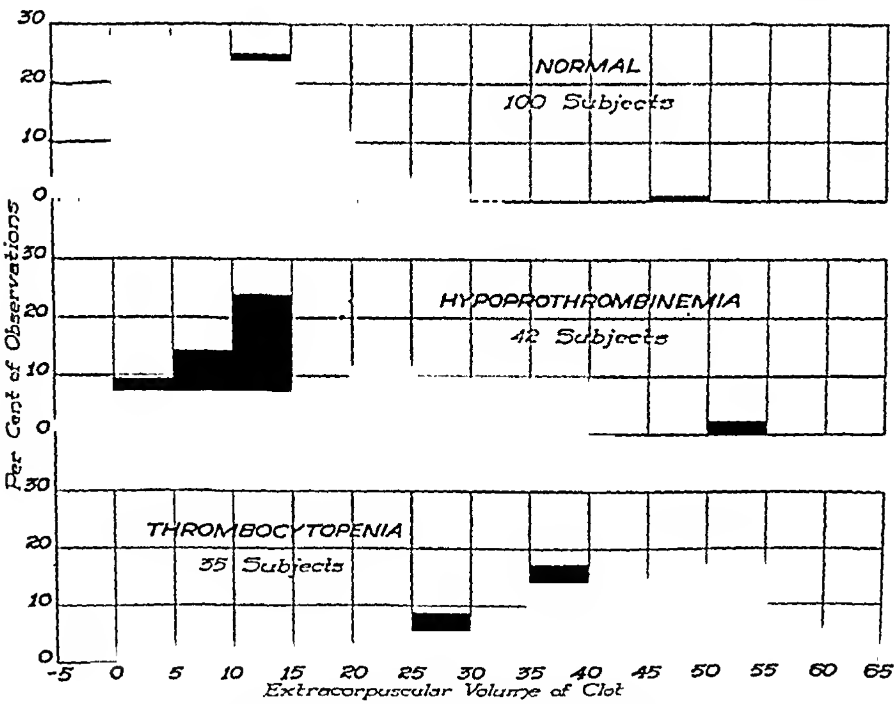

Fig. 4.—Frequency distribution of extracorpuscular volume of the blood clot in per cent of the total volume of the specimen.

When the packed cell volume is very low, and all other factors which influence clot retraction are normal, the maximum retractibility of fibrin may be achieved, and beyond this point there can be no further retraction regardless of the packed cell volume. It is obvious that this can happen only when clot retraction is excellent.

The volume occupied by the packed cells should be considered in estimating the degree of clot retraction. Failure to consider the effect of the cell volume on the volume of the clot may result not only in failure to detect deficient clot retraction in patients who have a normal cell volume, but also in the inability to recognize abnormal retraction in those who have severe anemia. Further-

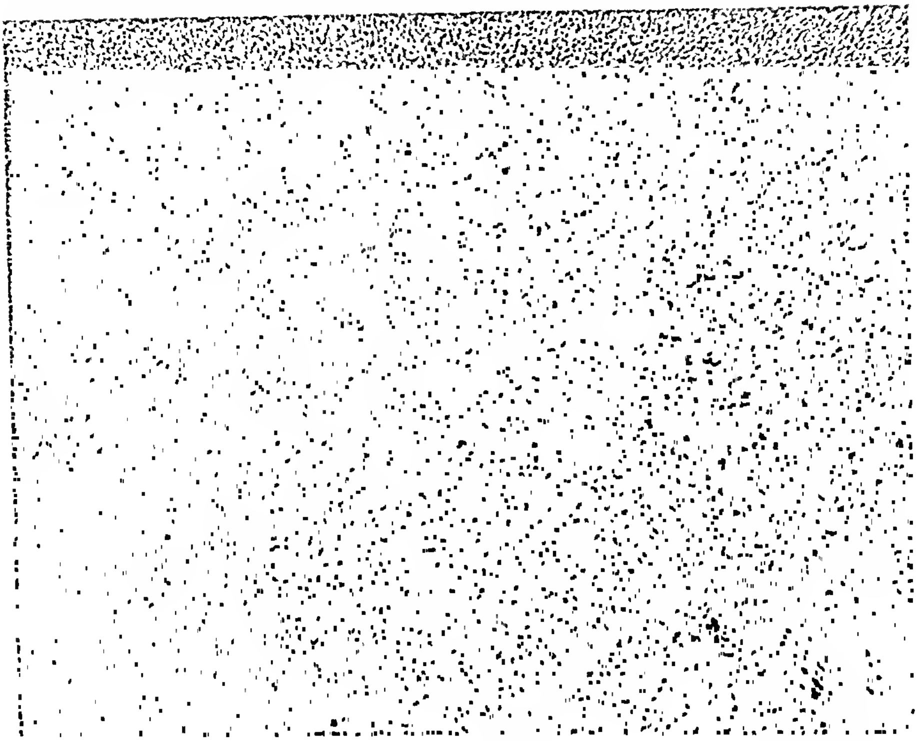

Fig. 5.—Section of a normal blood clot. Note the densely packed erythrocytes (×120).

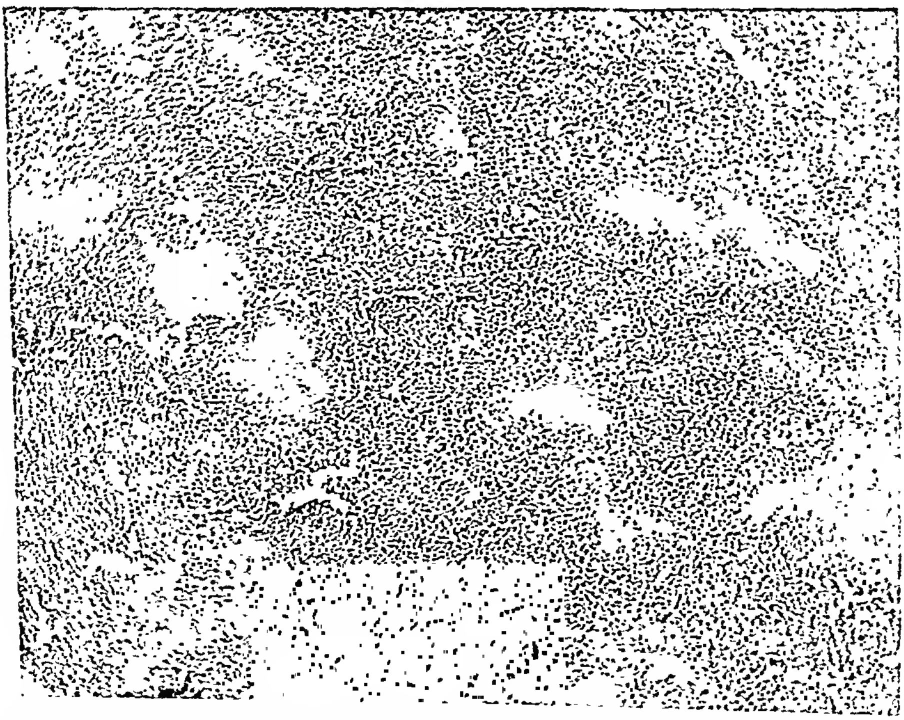

Fig. 6.—Section of a poorly retracting clot from a patient with thrombocytopenia. Note the fragmentation of the clot and the inclusion of large pools of fluid within the clot (×120).

more, unless the effect of the volume of the cells is appreciated, normal retraction may appear to be deficient in patients suffering from erythremia or leucemia.

In this study a highly significant relationship was found between diminished clot retraction and reduction in the platelet count. Tocantins[4] has made direct observations on the action of platelets in the mechanism of retraction of the blood clot. He states: "In the coagulation of blood from man and dog, soon after fibrin is laid down, *intact* platelets in the interior of the mass converge toward the fibrin needles, adhere to them and form large knots at their intersections. It appears that it is by thus strengthening the fibrin framework that platelets help to render the clot more rigid, firm and elastic. As the knots are being formed, the fibrin becomes bent, twisted and shortened. It is perhaps *while* this is going on and partly as a result of it, that the clot undergoes the visible reduction in volume (syneresis)." Furthermore, Tocantins[5] noted complete inhibition of blood clot retraction when antiplatelet serum was added to normal blood in vitro.

Two of us (P. M. A. and S. P. L.)[6, 7] have found that a significant correlation exists between the prothrombin concentration and the *clot retraction index* in patients suffering from obstructive jaundice and a variety of diseases affecting the liver. Boyce and McFetridge[1] noted that the prothrombin concentration was often diminished when the *serum volume index* was low. In the present study we have likewise observed in a significant number of patients suffering from a variety of diseases, an increase in the extracorpuscular volume of the clot when the prothrombin concentration was 50 per cent or lower. The reason for the frequent association of a diminished prothrombin concentration with deficient clot retraction may be due to incomplete conversion of fibrinogen to fibrin. The influence of the platelets on the degree of clot retraction is much greater than that of the prothrombin. It is possible that variations of the number of platelets within the normal range may be a factor in determining the degree of clot retraction, both in normal subjects and in those with hypoprothrombinemia.

Thrombocytopenia and hypoprothrombinemia are not the only factors concerned in clot retraction. We have observed patients in whom the prothrombin concentrations and the platelet counts were normal and in whom clot retraction was deficient; and conversely, we have studied patients in whom the prothrombin or platelet values were low and in whom the blood clots retracted normally. The recent observation of Rabinowitz[8] on the effect of amino acids on clot retraction may be of considerable aid in the solution of these problems.

SUMMARY

The blood clot is composed of cells, fibrin meshwork, and serum. The extracorpuscular volume of the clot is defined as that volume of the clot exclusive of its contained packed cells expressed as a percentage of the total volume of the specimen studied. Presumably, it is composed of serum occluded within the clot and a negligible amount of fibrin. The measurement of the extracorpuscular volume of the clot is a most significant factor in the analysis of the efficiency of blood clot retraction. In one hundred normal subjects the extracorpuscular mean volume measured 9.1 per cent and the standard deviation of this sample was 7.5 per cent; in 42 subjects who had prothrombin concentra-

tions of 50 per cent or less, the mean value was 18.2 per cent and the standard deviation was 12.4 per cent; and in 35 subjects, all of whom had platelet counts of 200,000 or less, the mean value was 38.9 per cent and the standard deviation of the sample was 14.1 per cent. We have arbitrarily considered the normal value to fall within two standard deviations of the mean (–5.9 to 24.1 per cent). Using this criterion, blood clot retraction was diminished in 13 of 42 patients who had hypoprothrombinemia, and in 30 of 35 patients who had thrombocytopenia.

DRY BUFFER SALT MIXTURES FOR USE IN BIOLOGICAL PREPARATIONS*

George A. Hunt, M.S., Ph.D., St. Louis, Mo.

In the preparation of many biological products the procedures specify the adjustment of a product to a given hydrogen-ion concentration. In many such procedures the accuracy of such an adjustment need not be great, provided the pH of the product does not exceed a given limit. Poorly buffered systems sometimes require time and considerable care to avoid exceeding the desired end point.

We have employed preparations of dry buffer salts which are useful, stable, and comparatively accurate. As we have not seen descriptions of dry salt preparations such as we use, and since these mixtures are very convenient, it seems worth while to describe them.

Sodium or potassium phosphate buffers were selected for pH values from 5 to 8. One per cent aqueous solutions of the salts selected for use were prepared and one solution was carefully titrated against the other in the presence of an indicator. The ratios of the buffer salts in solutions giving desired pH values were noted, and the amounts of the original dry buffer salts were determined. The solid buffer salts were powdered in a mortar, then weighed and mixed carefully in ratios determined by the titration, a different mixture

*From the Snodgras Laboratory of Pathology and Bacteriology, City Hospital, St. Louis. Received for publication, April 22, 1942.

being prepared for every pH value desired. For use, approximately 1 per cent of the dry buffer mixture of the required pH was dissolved in the product to be buffered.

In our work we wished to employ two buffer mixtures, one of pH 7.0 and the other of pH 7.6. Five cubic centimeters of 1 per cent $NaH_2PO_4.H_2O$ with 10 c.c. of 1 per cent Na_2HPO_4 (anhydrous) gave a pH value of 7.0, and 5 c.c. of 1 per cent $NaH_2PO_4.H_2O$ with 40 c.c. of 1 per cent Na_2HPO_4 (anhydrous) gave a pH of 7.6. Thus one part of powdered $NaH_2PO_4.H_2O$ mixed with two parts of powdered Na_2HPO_4 (anhydrous) gave a mixture which when dissolved in water produced a pH 7.0. Likewise, one part of the former salt and eight parts of the latter was used for a mixture giving a pH 7.6. These mixtures were prepared in 500 Gm. lots and stored in tightly stoppered bottles.

Two examples may serve to show some of the ways we have employed these mixtures. In the culture of amoeba[1] it was found that the presence of buffers was necessary for successful propagation using the method described by Tsuchiya.[2] A simple method of producing small amounts of broth buffered at pH 7.0, was to add a loopful of the pH 7.0 dry buffer mixture to each culture tube whenever excessive acid was formed in the culture.

In preparing Price-type gonococcus antigen for the complement fixation reaction according to the directions of Torrey,[3] it is necessary to dissolve the trichloroacetic acid precipitated fraction in saline and sodium hydroxide. The final pH of the product should not exceed 9.5 or the antigenic value depreciates.[4] It is easier to prepare an active, stable product by adding a small amount of dry buffer mixture of pH 7.6 to a saline suspension of the precipitate than to add sodium hydroxide carefully drop by drop to the same end point.

The greatest convenience of the dry buffer salt mixture lies in its ability to produce sufficiently constant pH value with widely varying concentrations of the mixture. The constituents of the mixture should be powdered, accurately weighed, and carefully mixed. When the mixture has once been prepared, it is often sufficient to estimate roughly the amount of the mixture needed and to add the dry mixture to the product to be buffered directly from the stock bottle without weighing.

A COMPARISON OF THE RYTZ, KAHN, AND COMPLEMENT FIXATION TESTS FOR SYPHILIS IN A LARGE SERIES OF ADULT MALES

Lewis E. Nolan, M.D., Montgomery, W. Va.

The Rytz test is a rapid, economical precipitation method for the serologic diagnosis of syphilis. The purpose of this paper is to compare the results of 18,681 Rytz, standard Kahn, and complement fixation tests on 5,644 adult male patients, examined over a period of eighteen months, and to determine the accuracy and value of the tests. All case records were carefully reviewed.

The directions given by Rytz[1] were rigidly adhered to in the performance of this test, the Kahn[2] test was performed according to instructions, and the complement fixation test was performed according to the modification of Matz.[3]

For purpose of comparison the Rytz test is read positive or negative; the Kahn test as positive, doubtful, and negative; and the complement fixation test as positive and negative, as recommended by the Committee on the Evaluation of Serodiagnostic Tests for Syphilis of the United States Public Health Service, cooperating with the American Society of Clinical Pathologists.*

Of the 5,644 males tested 98.9 per cent were of the Caucasian race, and 1.1 per cent were colored. The ages ranged from 23 to 95, with an average of 48 years. Each patient received a Rytz, Kahn, and complement fixation test. Some patients received two or more tests, accounting for the total of 18,681 tests.

The patients were divided into four groups: group I: history and clinical evidence of syphilis with positive serology; group II: history and clinical evidence of syphilis with negative serology; group III: no history or clinical evidence of syphilis but with positive serology; group IV: no history or clinical evidence of syphilis with negative serology.

Group I: A total of 846 tests were performed on 149 patients. The Rytz test was positive in the case of 144 persons, or 96.6 per cent; the Kahn test in 137,† or 91.9 per cent; and the complement fixation test in 133, or 89.2 per cent. The Rytz test was positive and the complement fixation and Kahn tests were negative in one case; the Rytz test was negative and the complement fixation test was positive in 3 cases; the Kahn test was positive and the Rytz and complement fixation tests were negative in 2 cases; the Kahn test negative and the complement fixation and Rytz tests were positive in no instances; the complement fixation test was negative and the Kahn and Rytz tests were positive in 7 cases; and the Wassermann test was positive and the Kahn and Rytz tests were

*Complement fixation test: four plus, three plus, two plus, one plus, all recorded positive; plus-minus, doubtful. Kahn test: four plus, three plus, two plus, all recorded positive; one plus and plus-minus, doubtful.

A COMPARISON OF THE RYTZ, KAHN, AND COMPLEMENT FIXATION TESTS FOR SYPHILIS IN A LARGE SERIES OF ADULT MALES

Lewis E. Nolan, M.D., Montgomery, W. Va.

The Rytz test is a rapid, economical precipitation method for the serologic diagnosis of syphilis. The purpose of this paper is to compare the results of 18,681 Rytz, standard Kahn, and complement fixation tests on 5,644 adult male patients, examined over a period of eighteen months, and to determine the accuracy and value of the tests. All case records were carefully reviewed.

The directions given by Rytz[1] were rigidly adhered to in the performance of this test, the Kahn[2] test was performed according to instructions, and the complement fixation test was performed according to the modification of Matz.[3]

For purpose of comparison the Rytz test is read positive or negative; the Kahn test as positive, doubtful, and negative; and the complement fixation test as positive and negative, as recommended by the Committee on the Evaluation of Serodiagnostic Tests for Syphilis of the United States Public Health Service, cooperating with the American Society of Clinical Pathologists.*

Of the 5,644 males tested 98.9 per cent were of the Caucasian race, and 1.1 per cent were colored. The ages ranged from 23 to 95, with an average of 48 years. Each patient received a Rytz, Kahn, and complement fixation test. Some patients received two or more tests, accounting for the total of 18,681 tests.

The patients were divided into four groups: group I: history and clinical evidence of syphilis with positive serology; group II: history and clinical evidence of syphilis with negative serology; group III: no history or clinical evidence of syphilis but with positive serology; group IV: no history or clinical evidence of syphilis with negative serology.

Group I: A total of 846 tests were performed on 149 patients. The Rytz test was positive in the case of 144 persons, or 96.6 per cent; the Kahn test in 137,† or 91.9 per cent; and the complement fixation test in 133, or 89.2 per cent. The Rytz test was positive and the complement fixation and Kahn tests were negative in one case; the Rytz test was negative and the complement fixation test was positive in 3 cases; the Kahn test was positive and the Rytz and complement fixation tests were negative in 2 cases; the Kahn test negative and the complement fixation and Rytz tests were positive in no instances; the complement fixation test was negative and the Kahn and Rytz tests were positive in 7 cases; and the Wassermann test was positive and the Kahn and Rytz tests were

*Complement fixation test: four plus, three plus, two plus, one plus, all recorded positive; plus-minus, doubtful. Kahn test: four plus, three plus, two plus, all recorded positive; one plus and plus-minus, doubtful.

†In addition, doubtful in 8 cases.

Received for publication, April 16, 1942.

negative in 3 cases. In only 6 cases, or 4 per cent of group I, is one test positive and the other two negative. It is evident that the Rytz and Kahn tests more closely agree than the precipitation tests and the complement fixation test.

In group II, 191 patients with history and clinical evidence of syphilis, many of them with previous records of positive serology, had received intensive antisyphilitic therapy and were discharged with seronegative findings, and at the time of this survey were negative serologically.

In group III careful study failed to elicit any history or clinical evidence of syphilis; however, 39 patients had positive serology by one or more of the three tests used. The Rytz test was positive in 27 patients; the Kahn test, positive in 19, doubtful in 7; and the complement fixation test, positive in 32. In this group again the results of the Kahn and Rytz tests were in close agreement, whereas the complement fixation was not in accord with the precipitation tests in 4 cases. The patients in this group had diagnoses of pneumonia, bronchitis, arthritis, appendicitis, undulant fever, duodenal ulcer, tuberculosis, pulmonary, renal calculus, and carcinoma. If the cases in this group are regarded as false-positive reactions, the percentage of the total number of patients tested is 0.4 per cent for the Rytz, 0.4 per cent for the Kahn, and 0.5 per cent for the complement fixation test.

In group IV, 5,265 patients gave no history or clinical findings of syphilis, and the serology was negative.

CONCLUSIONS

1. In a group of 149 syphilitic patients the Rytz test was positive in 96.6 per cent; the Kahn test, positive in 91.9 per cent and doubtful, or one plus, in 5.3 per cent; and the complement fixation test, positive in 89.2 per cent.

2. The so-called false-positive reactions in a group of 5,644 patients were 0.4 per cent for the Rytz, 0.4 per cent for the Kahn, and 0.5 per cent for the complement fixation test.

3. The Rytz test was found to give accurate results when compared with the Kahn and complement fixation tests and should be more widely recognized because of accuracy, speed, and economy in performance of tests for serodiagnosis of syphilis.

BLOOD PLASMA PIPETTE*

W. EARL MATTOX AND JOHN A. LEIGHTY, PH.D., INDIANAPOLIS, IND.

IN THE course of our work of preparing large amounts of dried human plasma for the armed forces of the United States, it became necessary to develop a pipette for the separation of plasma from cells, which not only would be rapid, but also would give a high yield of plasma. In most pipettes used heretofore, it has not been possible to draw the plasma rapidly, and at the same time be able to remove it down to within a few millimeters of the junction between the cell layer and plasma layer without also pulling cells up with the plasma.

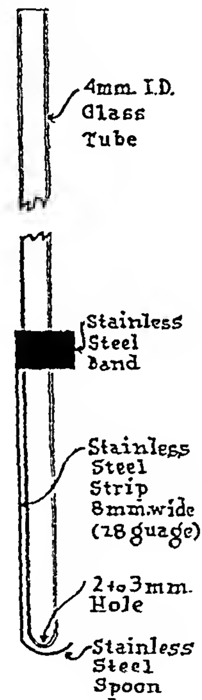

Fig. 1.

Fig. 1 shows a type of pipette which we are now finding very useful in large scale separation of plasma from cells. The stainless steel spoon and holder is made in one piece, and can be moved up and down on the glass tube. This pipette is most efficient when the end of the glass tube is just about touching the spoon.

A TECHNIQUE FOR THE EVEN DISTRIBUTION OF GASES THROUGH BACTERIAL CULTURES*

GREGORY SHWARTZMAN, M.D., AND WILLIAM BIERMAN, M.D.
NEW YORK, N. Y.

NUMEROUS workers have noted the influence of various gases upon the growth of microorganisms. These include Wherry and Oliver[1] (1916), Chapin[2] (1918), Kohman[3] (1919), Rendiger[4] (1919), and Rockwell and McKhann[5] (1921), who observed that the growth of meningococci and gonococci was best when the medium was exposed to 10 per cent carbon dioxide. Novy, Roehm, and Soule[6] made a thorough investigation of microbic respiration (1925), and Novy and Soule[7] (1925) studied in detail the respiration of *B. tuberculosis.* Robertson and Sia[8] (1924) determined the growth-inhibitory and bactericidal action of sera and leucocytes upon pneumococcus at different rates of rotation of tubes during incubation. Soule[9] (1928) described the influence of hydrogen and nitrogen upon bacterial growth. Magoon and Brunstetter[10] (1930) devised a special apparatus for the bubbling of gas through media.

We arranged a relatively simple apparatus for the passing of gas through broth cultures held within a water bath. Four large test tubes (25 by 200 mm., 1 inch by 8 inches, 50 ml. capacity) were suspended in a constant temperature water bath.[11] This number was used because it was found most convenient for our studies on the effect of various concentrations of the sulfonamides at different temperatures on the growth of *Streptococcus viridans.* A smaller or larger number could have been employed as well. Each tube, containing 30 c.c. of a 0.4 per cent glucose infusion broth with a pH 7.4, was inoculated with 1 c.c. of an eighteen-hour-old broth culture of *Streptococcus viridans.* The cultures maintained were kept at temperatures ranging from 37.5° C. to 41.5° C. The temperature of the water bath was held constant to within ± 0.05° C. by heaters, thermostat, and stirrer.

After a series of trials a gas mixture, consisting of 10 per cent carbon dioxide, 5 per cent oxygen, and 85 per cent nitrogen, was found favorable for the growth of *Streptococcus viridans.*† A tank containing these gases was connected to a regulator with a pressure gauge and a four-way outlet. From each of these outlets the gases flowed through separate wash bottles to the culture tubes. After bubbling through the cultures, the gas was permitted to pass through another series of wash bottles and then into the air. The constant slow agitation of the culture medium prevented the settling of the bacteria on the

---

Received for publication, April 24, 1942.

†A similar mixture was employed by Longsworth and MacInnes[12] in studies on the growth of *Lactobacillus acidophilus* at varying pH and temperature ranges.

bottom of the tube and insured an equal exposure of the organisms to the surrounding environment. The gas within the culture tube coming from the tank as well as that due to the metabolic activity of the organisms, passed continuously through the sidearm into the exhaust gas bottle.

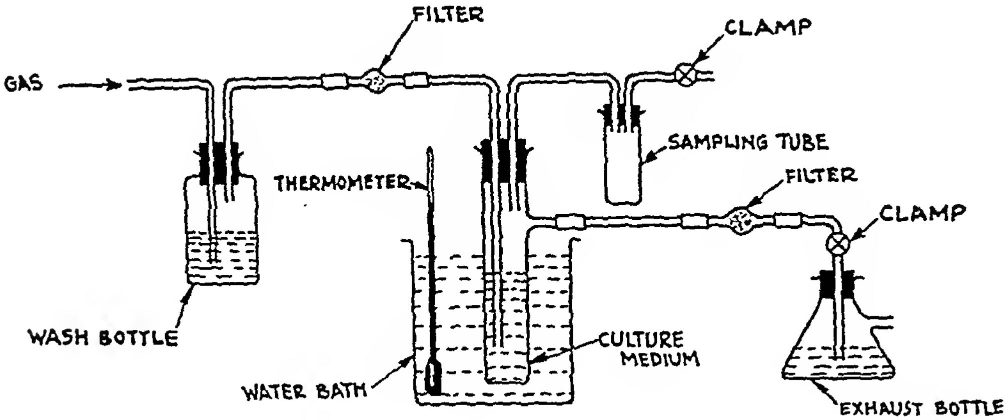

Fig. 1.—Gas coming from the tank passes through a wash bottle, then through a filter into the culture medium. The tube containing the medium is immersed in a water bath, the temperature of which is held constant by heating units, thermostat, and stirrer. The gas passes from the tube containing the culture medium through a side opening into an exhaust wash bottle from which it goes into the air. Closing the clamp on the tube going to the exhaust wash bottle causes the pressure within the culture tube to be raised, forcing the medium through another opening into the sampling tube. After the desired amount of culture medium collects in the sampling tube, the clamp on the tubing coming from it is closed, and the clamp on the tube going to the exhaust bottle is opened to re-establish the previous course of the flow of gas.

When it was necessary to remove a sample of the culture, the opening to an exhaust gas bottle was closed. This caused the building up of gas pressure within the culture tube which forced some of the medium through another opening leading to a sterile sampling tube. A clamp on the opening leading from this tube controlled the inflow. After the desired amount of medium had accumulated in the sampling tube, the outlet from this tube was shut off and the clamp restricting the flow of air into the exhaust bottle was opened.

This technique permitted the removal of the culture sample without contamination of the medium in the large culture tubes. Following the removal of the sample, another empty tube was substituted for it. The sample was thoroughly diluted in 0.04 per cent glucose infusion broth 10^{-6} and 10^{-7}. Poured blood agar plates were then made with the sample variously diluted for bacterial counts.

SUMMARY

A technique is described for the cultivation of microorganisms under the following conditions, namely: (a) constant slow agitation of the cultures during the entire period of growth; (b) carefully controlled temperature; (c) an even distribution of mixture of gases favorable for the microorganisms in the media; and finally, (d) easy removal of samples without any danger of contaminating the culture at any time during the cultivation.

CHEMICAL

RELATION OF THE CONCENTRATION OF STARCH SUSPENSIONS TO THEIR USE AS SUBSTRATES FOR THE AMYLASE OF THE DUODENAL CONTENTS OF INFANTS*

WILBURT C. DAVISON, M.D., DURHAM, N. C.

IN STUDYING the effect of the amylase of the duodenal contents of infants on the viscosity of starch suspensions in tenth-molar phosphate mixtures,† the successive measurements of viscosity must be plotted in order to determine the rate of change, since the time required to produce a definite amount of change was inversely proportional to enzymic activity; e.g., if 0.1 c.c. of an enzyme preparation required sixty minutes to reduce the initial viscosity 20 per cent, 0.2 c.c. reduced it a similar amount in thirty minutes.[1] On the other hand, the amounts of change in a definite time were not proportional; e.g., regardless of the strength of the enzyme, the viscosity of starch suspensions to which different amounts of amylase had been added, usually but not always, fell to that of the phosphate mixture in two to twelve hours, and then rose nearly to its original viscosity. This secondary increase in viscosity may be due to the viscosity of the end products of starch digestion, e.g., amylocellulose.

As the strength of an enzyme was inversely proportional to the *time* required to effect a definite percentage of change in the viscosity of the substrate but not to the *amount* of change in a definite period of time, an amylase unit was defined as that amount of enzyme which required sixty minutes to reduce the initial viscosity 20 per cent.[1] Sixty minutes and a 20 per cent change were used to define a unit since faster rates were difficult to determine accurately because the frequent measurements of viscosity consumed one to two minutes each, and the enzymic activity was continuing during the observations; slower rates allowed bacterial growth and other sources of errors to occur. Side reactions, which affected the viscosity, occurred with changes greater than 20 per cent in the substrate.

This linear relationship between the velocity of an enzymic reaction and the amount of enzyme used holds only when the amount of enzyme is much smaller than that of the substrate, so that all of it can combine with the latter.[2, 3] With a relative decrease in the concentration of the substrate, the velocity may be proportional to the square root of the concentration of the enzyme, the so-called Schütz and Borissov law,[4] e.g., increasing the concentration of *sucrose* up to 4 or 5 per cent increases the velocity of invertase reactions,[5] but concentrations

†All of these studies were made with the same preparation of soluble starch (Merck; made according to Lintner.

above that level decrease the rate of hydrolysis.[6] With colloidal substrates, as in the action of trypsin on gelatin, an increase in the concentration of the substrate also reduces the rate of hydrolysis, due either to the increased viscosity or to the products of hydrolysis.[3]

Viscosity determinations in enzymic measurements can be plotted against time in four ways: (1) As the "observed" viscosity (η, the outflow time of 5 c.c. of the starch-enzyme mixture); (2) the "net" viscosity (η-η_o, the outflow time of the buffer solution). (3) the "relative" viscosity (η/η_o), and (4) the "specific fluidity" (η_o/η-1). The resulting curves have the same general shape, and since the first method is simpler and as accurate as the other three, it was used in routine amylase titrations in infants.[7] As several viscosimeters were used in these titrations, the initial "observed" viscosities frequently were different,[4] and, therefore, were expressed as 100 per cent, and the subsequent measurements as percentages of the initial "observed" viscosity.

TABLE I

EFFECT OF THE CONCENTRATION OF STARCH SUSPENSIONS ON THE MEASUREMENT OF AMYLASE, BASED ON THE PERCENTAGE CHANGE IN THE "OBSERVED" VISCOSITY (FIG. 1)

CONCENTRATION OF THE STARCH SUSPENSIONS (%)	OUTFLOW TIME OF 5 C.C. OF THE STARCH SUSPENSIONS (η SEC.)	OUTFLOW TIME OF 5 C.C. OF THE BUFFER SOLUTION (η_o SEC.)	RELATIVE VISCOSITY η/η_o	TIME REQUIRED FOR A 20% REDUCTION IN THE INITIAL "OBSERVED" VISCOSITY (SEC.)	AMYLASE UNITS*

*The amount of enzyme which requires sixty minutes to reduce the initial viscosity 20 per cent.[1]

As shown in Table I and Fig. 1, in which the percentage changes in the "observed" viscosity were plotted against time, the addition of the same amount of duodenal contents to starch suspensions of different concentrations produced varied results. In the 1.04 per cent starch suspension the enzymic activity was similar to that in the other concentrations for twenty minutes and then stopped; agglutination occurred at the end of two hours. The rate of the enzymic hydrolysis of 2.5, 5.0, and 7.5 per cent starch suspensions was similar for the first forty minutes, but then the rate of enzymic activity in 2.5 per cent starch practically ceased. The rate of hydrolysis of 5 per cent starch was somewhat faster than that of 7.5 per cent starch for the first one hundred minutes and then became slower. As shown in Fig. 1, the solid and open points of the parallel titrations practically coincided.

After twenty-four hours at 34° C. all the starch-duodenal contents mixtures became agglutinated and their viscosity could not be determined. Some undigested starch remained in the 5 and 7.5 per cent suspensions but not in the

1.04 and 2.5 per cent suspensions after twenty-four hours; i.e., the addition of 5 c.c. of 1:62.5 Gram's iodine to 1 c.c. of the starch-duodenal contents mixtures produced a purplish blue color in the two former, but no color in the last two. All the substrates turned blue when the iodine solution was added before incubation with the duodenal contents.

As the times required for a 20 per cent reduction in the "observed" viscosity of 2.5, 5.0, and 7.5 per cent starch concentrations were more closely related than that for the hydrolysis of 1.04 per cent starch, the higher concentrations were used in other viscometric measurements of amylase.[7] A suspension with a relative viscosity of approximately 2.5 (Table I) was the easiest to work with as clogging of the viscosimeters occurred frequently with the heavier suspensions. Furthermore, the 7.5 per cent suspension became caramelized when autoclaved.

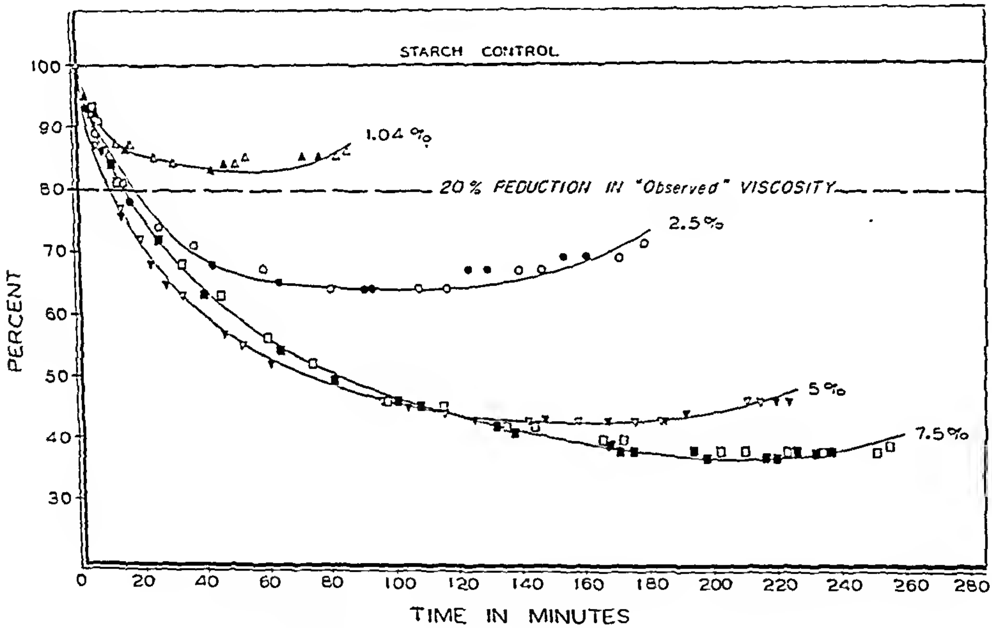

Fig. 1.—Effect of the concentration of starch suspensions on the measurement of amylase, based on the "observed" viscosity. One-tenth cubic centimeter of the same specimen of duodenal contents (diluted 1:20 with normal saline) was added to 10 c.c. of different starch concentrations, and the amylase activity was titrated viscometrically[1] in duplicate. The initial outflow times of the [illegible] tents mixtures in seconds (Table I) were plotted as 100 per cent (initial [illegible]), and subsequent measurements as percentages of this initial "observed" vi[illegible]. [illegible] of each pair of parallel titrations was plotted in solid points, and the other in open.

The relative viscosity of starch suspensions varied with the particular lot of soluble starch employed. A 2.5 per cent suspension of the starch used in Table I produced a substrate of this desired "observed" viscosity, but as much as 6 per cent of other samples of starch was required to produce a suspension of similar viscosity.[8] The digestibility of different lots of starch also has been found to vary, probably due to differences in the proportions of α- and β-amyloses and dextrins.[9] More uniform results have been reported by the use of substrates consisting of mixtures of two preparations of starch.[10]

The viscosity of starch suspensions made with cold phosphate mixtures was fairly constant, but boiling them, or preferably autoclaving them, for fifteen

minutes at 15 pounds pressure made the results uniform. The maximum viscosity was obtained by heating starch solutions to 93° C. Higher temperatures reduced the viscosity. However, starch suspensions, which were both boiled and autoclaved, were used routinely because they were more homogeneous and less likely to contain small lumps which clogged the capillary of the Ostwald viscosimeter, than those which were merely heated to 93° C. or boiled or autoclaved. Amylase titrations with boiled or autoclaved starch suspensions were similar.

The viscosity of autoclaved suspensions (without enzymes) of 1.04, 2.5, and 5 per cent starch was constant for twelve hours, but that of 7.5 per cent starch increased steadily for two hours and then remained constant for twelve hours. After twelve hours the viscosity of all the starch suspensions (without enzymes) increased, probably due to an increase in amylocellulose. However, if these starch suspensions were centrifuged after eight days, the viscosity of the supernatant fluid was the same as that of the phosphate mixture, suggesting that no more of the starch had dissolved. Occasionally a preparation was found which decreased in viscosity. Such suspensions, of course, were useless for amylase determinations.

Amylase determinations, employing starch suspensions less than twelve hours old, similarly made with the same preparation of Lintner starch on different days, were comparable, though far from accurate. Irregular results were obtained with older substrates, even though thymol was added to insure sterility. For example, the rate at which duodenal amylase produced a 10 per cent reduction in the viscosity of fresh and of nine-day-old starch suspensions was the same, but the time required to cause a 20 per cent reduction was much longer with the older preparation than with the fresh suspension.

The starch in these suspensions, made with Lintner soluble starch, apparently consisted of microscopically visible starch granules and ultramicroscopic colloidal particles. The latter probably represented the fraction attacked by amylase, for after the enzyme had reduced the initial viscosity of a starch suspension until it was practically the same as that of the phosphate mixture, the number of starch granules was not reduced. Furthermore, if a starch suspension which had been split by amylase was allowed to stand a few hours, the starch granules sank to the bottom of the tube, leaving the supernatant fluid water clear, in contrast to the supernatant fluid of an unsplit suspension which remained opalescent indefinitely, even though diluted with tenth-molar phosphate mixture until its viscosity was the same as that of the starch suspension which was split by amylase. Because of these two types of starch, it was not possible to determine the actual starch content of starch suspensions at any stage in enzymic reactions by merely comparing their viscosity curves with those of suspensions of unsplit starch of known concentrations.[8]

CONCLUSION

A starch suspension with a relative viscosity of approximately 2.5 and less than twelve hours old was the most suitable for the viscometric titration of the amylase of the duodenal contents of infants, but the results were not always accurate. However, viscometry[1] is preferable to other methods.[13]

Sufficient soluble starch (Merck; made according to Lintner) to make a suspension with a relative viscosity of approximately 2.5 (2 to 6 Gm., depending on the preparation) should be added to 100 c.c. of tenth-molar phosphate mixture (40 c.c. M./10 KH_2PO_4 + 60 c.c. M./10 Na_2HPO_4). The suspension should be shaken vigorously until it becomes homogeneous (usually one minute), boiled for one to two minutes, and autoclaved for fifteen minutes at 15 pounds pressure; one or two thymol crystals should be added, and the suspension filtered, while hot, through one thickness of muslin. After it has cooled to about 34° C, 10 c.c. portions should be pipetted into clean test tubes and kept in the water bath for at least one hour and not more than twelve hours before being used. The final reaction of this substrate is pH 6.8 to 7.0, which is optimal for the amylase of the duodenal contents of infants.[11] If the amylase of taka-diastase is being titrated, phosphate mixtures of pH 3.0 to 4.8 should be used.[12] All the titrations should be done with the same lot of soluble starch. Other concentrations of starch have been used and various methods of preparation tried, but the above appeared to be the most satisfactory.

I wish to thank Dr. Elizabeth Torrey (Mrs. J. G. Andrews) for plotting the enzyme curves and calculating the units; Mrs. H. A. King and Mr. E. H. Clark for the drawings; Dr. Hans Neurath, Dr. Paul Gross, Dr. D. G. Hill, Mr. J. H. Neese, and Mr. W. V. Singletary for verifying the calculations.

A METHOD FOR THE DETERMINATION OF CERTAIN SULFONAMIDES IN BILE*

Haddon M. Carryer, M.D., and Arnold E. Osterberg, Ph.D.
Rochester, Minn.

With the increasing use of sulfonamide compounds in the treatment of infection, a knowledge of the excretion of these drugs in the bile has assumed greater importance. A method for determination of sulfanilamide in bile was presented by Ivy and one of us (H. M. C.)[1]; this was a modification of the method of Doubilet. With the recent refinements[2] in chemical procedures employed in the determination of sulfanilamide, and with the introduction clinically of several new drugs in this field, it seems advisable to extend the previously published method in order to include the new improvements and to test the applicability of the method to the new drugs.

We have found the following procedure satisfactory for the quantitative determination of sulfanilamide, sulfapyridine, sulfadiazine, and sulfathiazole in bile. With the last-named drug an additional step must be used.

METHOD

Place 5 c.c. of the bile to be examined in a 50 c.c. volumetric flask. If concentrations of the sulfonamide compound of 2 mg. per 100 c.c. or less are expected, use 10 c.c. of bile. Add 3 c.c. of 2 N potassium hydroxide. Add 3 c.c. of a 40 per cent solution of zinc sulfate drop by drop, with constant agitation. Add portions of hot water and agitate the precipitate to insure solution of the drug. Dilute to approximately 45 c.c. Then add 3 c.c. of normal potassium carbonate. Add a drop of phenolphthalein indicator solution. Dilute when cool to exactly 50 c.c. Filter. Acidify the filtrate exactly to phenolphthalein by the addition of 2 or 3 drops of 4 N hydrochloric acid. By acidifying after filtration, pigmented substances are eliminated by filtration and do not go into solution as they would if the acid were added before they are removed. Dilution of filtrate by acid solution may be considered negligible.

To 10 c.c. of the filtrate add 1 c.c. of tenth-normal hydrochloric acid. Agitate for a moment until no more effervescence is noted. This will prevent interference from bubbles in the photelometer cups in a later stage. Then add 1 c.c. of a freshly prepared 0.1 per cent solution of sodium nitrite. Agitate and allow to stand for three minutes. Add 1 c.c. of a 0.5 per cent solution of ammonium sulfamate. Agitate and allow to stand for two minutes. Add 1 c.c. of a 0.4 per cent aqueous solution of N-(1-naphthyl) ethylenediamine dihydrochloride. The color developed is read immediately against simultaneously prepared aqueous standards in a colorimeter or, if facilities are available, with a photelometer equipped with a filter.

*From the Mayo Clinic, Rochester.

Received for publication, May 20, 1942.

When sulfathiazole is the drug to be determined, a slight modification of the method is necessary because of the insolubility of the dye product formed. It is necessary to add 5 c.c. of ethyl alcohol to the 10 c.c. portion of filtrate and to the 10 c.c. portion of the standard solution for comparison in the colorimeter before addition of the solution of sodium nitrite. This will insure the solution of dye in subsequent procedures.

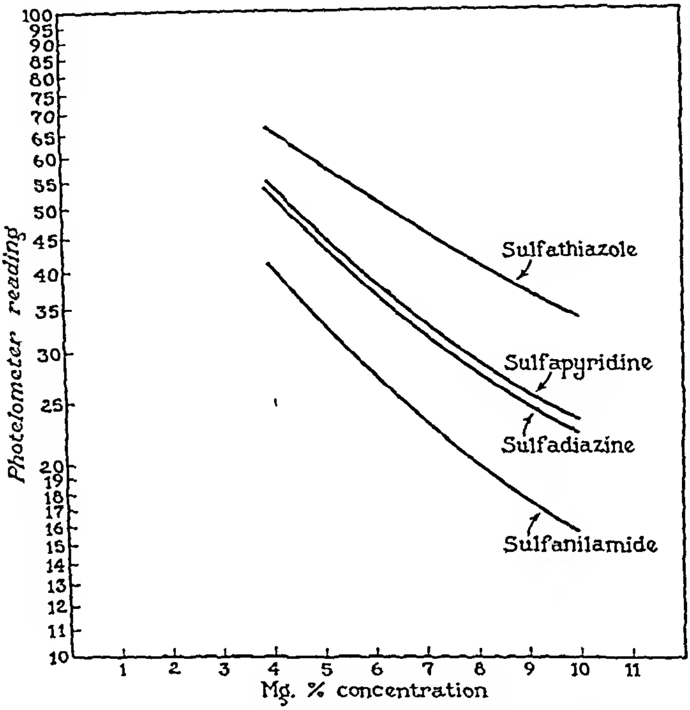

Fig. 1.—Relationship of concentrations of sulfonamides and readings on the photelometer.

This method as described will determine only the drug in its free form; acetylated drug must be hydrolyzed if the total content of drugs is to be found. If this is desired, it is necessary to add to the 10 c.c. of filtrate 0.5 c.c. of 4 N hydrochloric acid and place in a bath of boiling water for one hour. After cooling, make the volume 10 c.c. Proceed as with 10 c.c. of original filtrate with the method described.

Should the colorimeter be used in this determination, the following formula may be employed:

$$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times \text{strength of standard}$$

that is, 0.06 mg. × 100 = concentration of unknown in milligrams per 100 c.c.

We have found the photelometer accurate in this determination when a green filter allowing maximal transmission of 530 Å units is employed. As the dye produced in the reaction has a maximal absorption of 545 Å units,[2] a considerable amount of extraneous color is eliminated suitably. When this filter is employed, the error introduced by the use of aqueous standard rather than bile filtrate will average 1.8 per cent and will not exceed 3 per cent.

Bile which was known to contain 10 mg. per 100 c.c. of the afore-mentioned sulfonamide compounds was used to test the accuracy of the method (Table I). The method is more accurate when sulfanilamide, sulfapyridine, or sulfadiazine is present in the bile than when sulfathiazole is present.

TABLE I

RECOVERY OF SULFONAMIDE COMPOUNDS FROM BILE IN WHICH THE CONCENTRATION WAS KNOWN TO BE 10 MG. PER 100 C.C.

SAMPLE	MILLIGRAMS PER 100 C.C.			
	SULFANILAMIDE	SULFAPYRIDINE	SULFADIAZINE	SULFATHIAZOLE
1	9.7	9.3	9.6	7.7
2	10.0	10.1	10.2	8.1
3	9.7	9.9	9.8	7.8
4	9.5	9.2	9.8	7.3
5	9.7	9.3	9.9	8.0
6				8.5
7				7.8
8				8.1
9				8.0
10				8.6
Average	9.7	9.6	9.8	8.0

The curves from which these data were read are given in Fig. 1. Because of a slight variation in photoelectric cells in these photelometers, a curve should be established for each instrument.

An attempt was made to determine the accuracy of photelometric curves for the sulfonamides on the semilogarithmic graph. By introducing factors to correct for differences in dilution, as in the case of sulfathiazole, and for differences in molecular weight, identical curves should be established. An arbitrarily selected intensity of color was chosen on an abscissa of the graph which was intersected by all curves plotted. Log 4.00 was chosen. The concentration of the drugs at this level of color intensity was then converted by the afore-mentioned factors to terms of concentration of sulfanilamide.

The concentration of all drugs when converted to terms of sulfanilamide and read at the color intensity of log 4.00 varied only slightly. The concentration thus obtained was 3.99 mg. per 100 c.c. ± 0.17 mg. per 100 c.c.

SUMMARY

A method has been presented by which the concentration of sulfanilamide, sulfapyridine, sulfadiazine, or sulfathiazole in bile may be determined. This method has been tested with solutions of known concentration and percentage rates of recovery have been determined.

AN OSMOMETER FOR USE WITH SERUM AND ITS SUBSTITUTES*

Henry S. Simms, Ph.D., Raymund L. Zwemer, Ph.D., and
Bertrand E. Lowenstein, M.D., New York, N. Y.

THE present use of "banked blood," stored or dried plasma, and plasma substitutes in the treatment of shock from trauma, burns, or hemorrhage has as its aim the restoration and maintenance of normal blood volume. This aim is accomplished by the injection of solutions which contain, not merely salts and sugars, but also some material which produces a sufficient "protein osmotic" or "oncotic" pressure (erroneously called "colloid osmotic pressure"†) approximately equal to that of normal plasma.

In the case of serum or plasma the "protein osmotic" pressure can be estimated by calculations based on the content of albumin and of globulin. The albumin is responsible for about 80 per cent of the pressure. A rough approximation can be made also from the protein content, as determined by protein nitrogen or plasma specific gravity. However, with dried plasma, gelatin, pectin, or other blood substitutes, the osmotic pressure can best be determined by direct measurement.

The use of a long tube attached to a membrane[1] requires twenty-four hours or longer to reach equilibrium, so that bacterial action and dilution of the serum can cause serious errors. Turner[2] in 1932 devised a method for counterbalancing the pressure so as to reach equilibrium in five to twenty hours. In 1936 Sumalt and Landis[3] constructed an ingenious, but complicated, apparatus which automatically counterbalanced and recorded the pressure until equilibrium was reached. Hepp[4] in 1936 invented a micro-osmometer in which ultrafiltrate from a sample of serum was sucked through a large membrane into a capillary. The balancing pressure was then adjusted until the capillary meniscus was seen through a microscope to be stationary. Peters and Saslow[5] claimed to obtain good results with this osmometer of Hepp. There is, however, the danger that

*From the Departments of Pathology and of Anatomy, College of Physicians and Surgeons, Columbia University, New York.

This work has been aided by grants from W. R. Warner and Company, the Upjohn Company, and the John and Mary R. Markle Foundation.

†We dislike all three of these terms which are applied to the osmotic pressure observed when a nondiffusible ion on one side of a membrane is in equilibrium with diffusible inorganic electrolytes. It was stated by Peters and Van Slyke (Quantitative Clinical Chemistry, Vol. I, page 659) that of the 25 mm. (of mercury) osmotic pressure exerted by blood plasma against isotonic saline solutions, 20 mm. pressure is due to the protein molecules while 5 mm. pressure results from the unequal distribution of diffusible ions according to Donnan's law (Zschr. f. Electrochemie 17: 572, 1911). The latter phenomenon was further studied by Jacques Loeb (J. Gen. Physiol. 3: 667, 691, 827, 1920; 4: 73, 1921).

The term "protein osmotic pressure" is applicable only to systems, such as plasma, where the nondiffusible ions are proteins. The term "colloid osmotic pressure" is particularly objectionable, since it implies that the pressure involves a colloidal phenomenon. Actually the large ion need not be a protein (Donnan used a dye). Perhaps "oncotic pressure" is the least objectionable term in current usage which is applied to the phenomenon. However, this connotes "swelling" and does not distinguish, except by usage, between the observed osmotic pressure when only the large ions are nondiffusible and the theoretical osmotic pressure due to all ions and molecules. We prefer the term "Donnan pressure" but realize that this also is not clearly defined.

the large capillary correction (about 90 mm. of water) and also the use of rubber connection may cause appreciable errors. The errors of the Krogh apparatus were discussed by Wells.[6]

The apparatus herewith described (Fig. 1) was designed to give rapid and accurate results which involve no capillary correction. It uses only 1 to 2 ml. of serum or other fluid, and gives accurate readings within fifteen minutes.

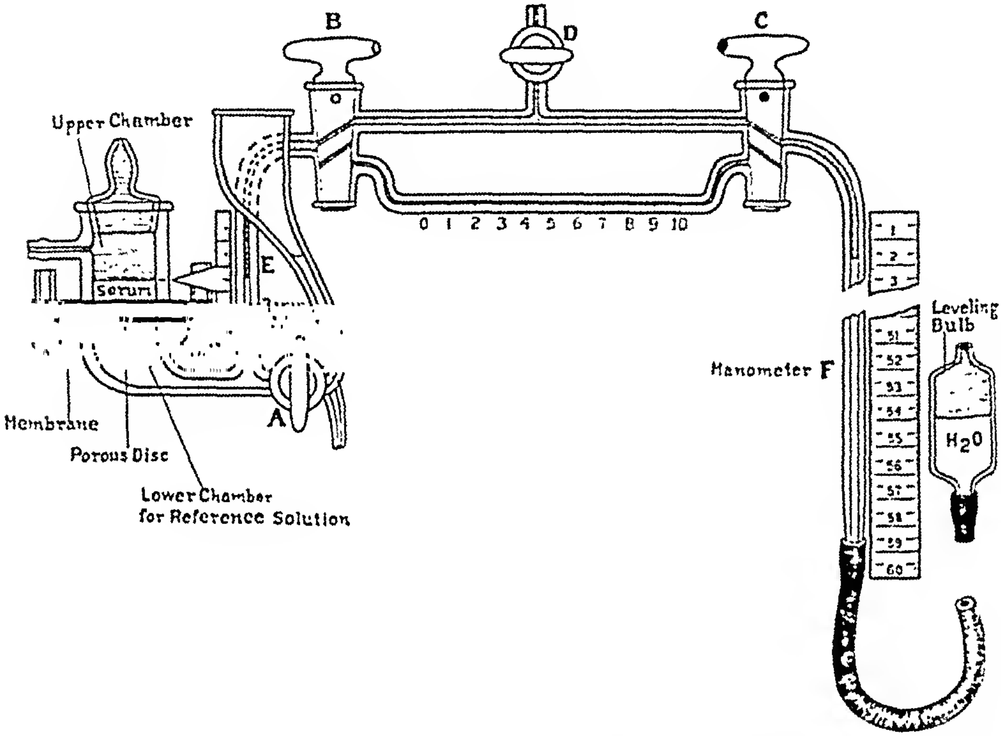

Fig. 1.—The S.Z.L. osmometer. This is firmly supported on a wooden stand not shown in the diagram. Air spaces are shaded, solutions are shown white and the kerosene drop is indicated in black. Detailed description is in the text. The centimeter divisions on the two scales may serve to indicate the dimensions of the apparatus.

DESCRIPTION OF OSMOMETER

In Fig. 1 the osmometer may be seen to consist of the following parts: a removable upper chamber, for the serum or other solution, with an inside diameter of 25 mm. The side arm and the hole in the cover permit the flow of carbon dioxide—air mixture over the solution to maintain pH. The upper chamber is clamped to a lower chamber with the membrane in between glass surfaces which are ground flat. The membrane is supported by a porous disk of fritted pyrex or alundum. The lower chamber is used for the "reference fluid" (such as serum ultrafiltrate or similar physiologic solution), which is introduced from a filling cup through stopcock *A*. The same stopcock serves to drain the chamber. The lower chamber is connected through tube *E* and stopcocks *B* and *C* to the manometer tube *F*, to which a small leveling bulb is attached with heavy walled ⅛ inch rubber tubing. Tubes *E* and *F* should have the same inside diameter (about 3 mm.). Stopcocks *B* and *C* are connected by an upper, 2 mm. bore, tube (having an outside stopcock *D*) and also by a lower capillary tube

in which a drop of colored kerosene serves to indicate motion. The membrane area is 1,000 to 1,700 times the capillary cross section and an observable movement of 0.2 mm. in the capillary represents a displacement of only 0.003 to 0.005 per cent of the serum volume.

METHOD FOR USING OSMOMETER

The osmometer is prepared for use by first cleaning it and then attaching it to a firm board. The leveling bulb is filled with distilled water and is supported by an adjustable clamp. A small drop of kerosene, colored with scarlet red, is introduced into the horizontal capillary tube by removing the plug of stopcock *B* and using a syringe with a bent needle or a dropper with a fine bent tip. By lowering the leveling bulb slowly, the drop is drawn into the tube; it should be 5 to 10 mm. long. No kerosene should remain at the end of the tube near the stopcock.

To fill the osmometer for the zero reading, the porous disk is put in place and the lower chamber is filled with the desired "reference fluid," such as serum ultrafiltrate[7] or a physiologic solution such as is used in these laboratories.[7] This "reference fluid" is introduced from the filling cup through stopcock *A* while stopcocks *B* and *D* are open. A prepared collodion membrane (see below) is then placed over the disk in such a manner as to exclude bubbles of air. The upper chamber is clamped in position and into it 2 or 3 ml. of the "reference fluid" is placed. With *B* and *C* open across the upper tube (and *D* closed) the leveling bulb is lowered to give a negative pressure of about 200 mm. of water for two or three minutes. This pulls the membrane down tight onto the disk. Then stopcock *B* is closed and *D* is opened. The leveling bulb is then raised to bring the water near the top of the manometer tube *F* and stopcock *D* is closed. The "reference fluid" in the vertical tube *E* should be at approximately the level of the fluid in the upper chamber. It can be adjusted by stopcock *A*.

A "zero reading" is taken by opening stopcock *B* and *C* to the lower (capillary) tube and then adjusting the leveling bulb until the drop of kerosene remains stationary for five minutes. If the drop moves to the right, the bulb should be raised. If it moves to the left, the bulb should be lowered. A half minute should elapse after each adjustment before the first observation is made, and the next reading is taken at least a minute later. With a little practice the amount of adjustment required can be estimated from the rate of movement of the kerosene drop. When there has been no movement for five minutes, a record is made of the height of the water column in the manometer above the water surface in the leveling bulb. The height of the "reference fluid" in tube *E above* the fluid surface in the upper chamber is also recorded and *subtracted* from manometer *F* reading to obtain correct "zero reading." If the fluid in *E* is below that in the upper chamber, the difference is added to the manometer reading.

The zero reading should equal zero. Any deviations may be due to an air bubble under the membrane, or a failure to draw the membrane down flat against the disk, or to kerosene at an end of the capillary tube. The zero reading should be repeated after momentarily reversing stopcocks *B* and *C*

and, if desired, readjusting the water level while D is open. With the pressure set at the previous reading there should be no movement of the kerosene drop.

Readings on the unknown solutions are taken next. Stopcock B is closed, the fluid in the upper chamber is drawn off, and the membrane is dried quickly with filter paper. One to 2 ml. of the serum or other unknown solution is introduced immediately. B and C are opened to the upper tube, and the leveling bulb is lowered to approximately the expected pressure. Adjustments are then made, as described above, preferably alternating the adjustments above and below the final reading, thus making sure that there is a real Donnan pressure. When the kerosene drop remains stationary for at least five minutes, the manometer is read. It can be checked by repetition of the procedure.

The membrane can be used for a number of unknown solutions, each solution being removed and the membrane wiped with filter paper before the next solution is placed in the upper chamber. It is well to start with the more dilute solutions and finish with the more concentrated solutions, or else wash the membrane with the "reference fluid" between samples.

Cleaning of the osmometer after use can be done with cleaning solution, which is allowed to stand in the filling cup and lower chamber and is drawn up into tube E. There is less danger of affecting the pH if 0.01 molar sodium hydroxide is used, instead of dichromate cleaning solution, and followed by 0.02 molar acetic acid, rinsing with distilled water after each solution.

Membranes. We obtained best results with membranes made from Merck's C.P. 5 per cent collodion solution on machines previously described.[7] These tubular membranes are cut into 50 to 55 mm. squares or circles and are preserved under distilled water, never being allowed to dry out. For twenty-four hours or more before use, the membranes are allowed to soak in physiologic solution (preferably "Z solution"[7]). This insures saturation of the membranes with calcium and permits a rapid equilibrium which is not otherwise possible. The Viscose Corporation sausage skin and No. 600 DuPont cellophane also gave good results, but these have a pore size of about 2 mμ, which may account for the longer time necessary for a detectable movement of the kerosene bead to appear.

Flat membranes, similar to the first type but less satisfactory, were made by pouring the collodion solution onto mercury in a Petri or similar dish. One milliliter of collodion solution covers 6.5 to 7 sq. cm. of surface. Hence a dish with a diameter of d cm. will require 0.12 d^2 ml. Allow to dry for thirty minutes in a dust-free atmosphere, soak in 50 per cent alcohol for fifteen minutes or longer, then wash with distilled water.

Pore size of the membranes. The osmometer can be used for the measurement of alleged pore size of membranes, as it is commonly rated. Distilled water is placed in both upper and lower chambers, using a membrane which has soaked in distilled water. After a zero reading has been taken, a negative pressure of about 200 mm. (H) is established and the time t in seconds required to move the kerosene drop a given distance L is observed. Using another sample of the same membrane (s mm. square), the thickness l is measured with a micrometer and the water content W is determined by weighing before and after drying. All measurements are in millimeters and the weight is in milligrams.

The pore diameter (in millimicrons) is given by the equation

$$d = \left(56{,}600 \, \frac{d_c}{d_m}\right) l \; s \sqrt{\frac{L}{W \, H \, t}}$$

The ratio of the capillary diameter d_c to the effective membrane diameter d_m can be permanently determined for each apparatus by estimating the capillary diameter as follows: W' milligrams of mercury is introduced into the capillary tube and the length l_c of the column is noted. The diameter in millimeters is then equal to $d_c = 0.307 \sqrt{W'/l_c}$.

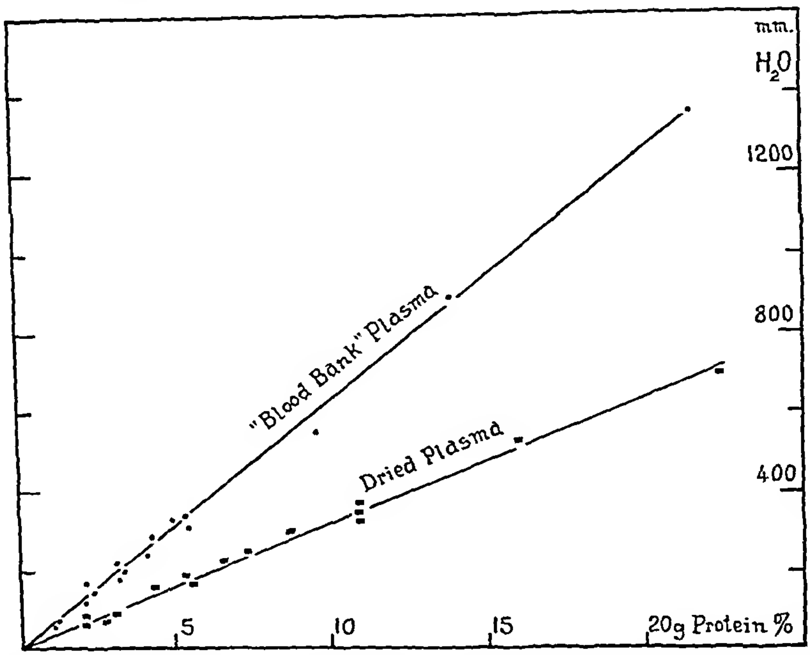

Fig. 2.—The Donnan osmotic pressures of various concentrations of human plasma, plotted against grams of protein per 100 c.c. Upper curve: Citrated human plasma from a "blood bank." The higher concentrations were obtained by dialysis in a collodion bag. Lower curve: Dried human plasma which had been found to be unsatisfactory by other tests. The various concentrations were obtained by weighing the dried powder.

In all cases the protein concentration was checked by the Barbour and Hamilton falling-drop determination of density.

Linear curves were also obtained with dilutions of horse serum, cat plasma, and a sample of approved dried human plasma.

RESULTS

Fig. 2 illustrates the results obtained with this apparatus. The curve for blood plasma at various concentrations above and below the normal level is seen to give consistent values. Another curve in Fig. 2 shows some observations on dried plasma at various concentrations. These values, although lower than for normal plasma, are consistent among themselves. Readings were found to be reproducible within 5 mm. of water.

In addition to the consistency of the readings it will be noted that throughout the range from zero up to four times normal concentration, the osmotic pressure is a linear function of the protein concentration, as measured by specific gravity. This agrees with the statement of Homer Smith and co-workers[8] and is contrary to the claim of Adair, Adair, and Greaves.[9] Further presentation of results will be included in future papers.

SUMMARY

An apparatus for measuring the "protein osmotic" or "oncotic," pressure of serum or other solutions is described. This apparatus requires only one or 2 ml. of fluid; it involves no correction for capillarity and it gives, in fifteen minutes, values which are reproducible within 5 mm. of water.

Rapid equilibrium is produced by exerting a negative pressure on the "outer" or "reference fluid" by means of a leveling bulb. When the equilibrium pressure is found, a drop of kerosene in a horizontal capillary tube becomes stationary. The Donnan osmotic pressure is then read from a manometer.

THE MICRODETERMINATION OF GOLD IN BIOLOGICAL TISSUES*

WALTER D. BLOCK, PH.D., AND OLIVER H. BUCHANAN, M.S.
ANN ARBOR, MICH.

IN ORDER to determine small quantities of gold in tissues it was found necessary to modify the procedure described by Block and Buchanan[1] for the microdetermination of gold in blood and urine. The modifications were primarily in the digestion of the tissues, but the final procedure so differed from the original method in details that it is thought advisable to report the complete procedure with typical recoveries for tissues.

PROCEDURE

Digestion.—The tissue (0.5 to 10 Gm.) to be analyzed is placed in an accurately calibrated 100 c.c. Kjeldahl flask whose neck has been shortened to 5 or 6 cm.[1] Ten to 20 c.c. of concentrated nitric acid and a few drops of caprylic alcohol are added and the tissue is allowed to stand for a few hours until solu-

Received for publication, May 25, 1942.

tion has occurred. Ten to 15 c.c. of concentrated sulfuric acid are introduced into the flask which then is heated on a Kjeldahl digestion rack until the tissue is thoroughly charred. After the digest is cooled, a 30 per cent solution of hydrogen peroxide (Superoxol) is added drop by drop until the solution is water clear. The solution is evaporated to dryness over a microburner. The sulfuric acid fumes are removed by inserting into the neck of the flask a glass tube which is connected through a water trap to a water pump.[1] The contents of the flask are then treated with aqua regia to convert the gold to the chloride. If the tissues contain amounts of gold less than 200 micrograms, the color is developed and read as previously described[1] directly with the entire contents of the digestion flask. However, if larger amounts of gold are present, the aqua regia solution in the flask is heated to boiling, cooled, and transferred to a 100 c.c. volumetric flask. The Kjeldahl flask is rinsed twice with 15 to 20 c.c. of boiling aqua regia, the washings are added to the volumetric flask, which is made to volume with distilled water. Aliquots containing 50 to 150 micrograms of gold are transferred to the shortened graduated 100 c.c. Kjeldahl flasks and evaporated to dryness. Remaining traces of sulfuric acid are removed as before and the gold is reconverted to auric chloride by boiling with aqua regia. The aqua regia solution of this aliquot is then used to develop the color. Any fatty or muscular tissue (legs, gastrointestinal tract) is treated in the same fashion, except that the digestion is carried out in a 300 c.c. Kjeldahl flask with the addition of selenium as a catalyst. After evaporation to dryness with complete removal of the sulfuric acid, the residue is put into solution by boiling with three 40 c.c. portions of aqua regia. All the washings are collected in a 250 c.c. volumetric flask, made to volume with water, and aliquots containing 50 to 150 micrograms of gold are transferred to the special 100 c.c. Kjeldahl flasks. The procedure is then carried out as already described for other tissues.

This same procedure can be applied to large organs or carcasses of small experimental animals as well as to dried animal and human feces, the only modification being that a 500 c.c. Kjeldahl digestion flask is used.

Development of Color.—This is accomplished[1] by the addition of 75 c.c. of distilled water to the precipitate in the 100 c.c. Kjeldahl flask in order to dissolve the inorganic salts. Three-fourths cubic centimeter of hydrochloric acid (1:4), 8 c.c. of potassium fluoride (10 per cent), and 1 c.c. of o-dianisidine solution (0.1 per cent) are then added to the flask. The volume is made up to 100 c.c. with distilled water, the flask is stoppered and the solution thoroughly mixed. The solution is then transferred to a colorimeter absorption tube, filling the tube to within 1 to 2 cm. of the top. After stoppering, the pink color, which reaches its maximum intensity within three to ten minutes, is read in the Evelyn photoelectric colorimeter with filter 440 and a center setting of 76.

Special attention should be called to the amount of 1:4 hydrochloric acid added in the color reaction, for the rate of color development and fading depends upon the ratio of fluoride to acid. The amount of acid which remains in the flasks after conversion with aqua regia depends upon the amount of inorganic salts present. A maximum color will develop in six to eight minutes if 0.75 c.c. of 1:4 hydrochloric acid is used in direct determination of gold in tissues or urine. In determinations of gold in carcasses or feces 1.25 c.c. of the

acid must be added, and in the case of diluted tissues, 2.5 c.c. It is best to read the color at one-minute intervals during the development until the maximum color is reached and fading begins. Since it requires only fifteen seconds to make a reading, four tubes may be easily read at minute intervals.

TABLE I

RECOVERY OF KNOWN AMOUNTS OF GOLD ADDED TO TISSUES AND EXCRETA OF THE WHITE RAT

	GOLD ADDED	GOLD FOUND			GOLD ADDED	GOLD FOUND	
	mg.	mg.	per cent		mg.	mg.	per cent

	5.000	4.855	97.1				

*Gold added to urine and feces collected over a two-week period.

RESULTS

Table I gives the percentage recovery of various amounts of gold added to tissues and excreta of the white rat. The recoveries vary from 90 to 100 per cent, except in one case, in which 0.5 mg. of gold was added to feces. In this instance recovery was 81.3 per cent. This comparatively low recovery is probably associated with the inhibition of color development due to the presence of large amounts of inorganic salts in relation to the small quantity of added gold.

CONCLUSION

The method of Block and Buchanan for the microdetermination of gold in urine and blood has been modified to apply to tissues and feces. Recoveries of added gold by this procedure vary from 90 to 100 per cent.

A STORAGE VESSEL FOR BLOOD*

Frederic E. Holmes, Cincinnati, Ohio

THE slow rate of diffusion of gases into oil delays, but does not entirely prevent, measurable changes in the gas content of specimens stored under oil. The vessel shown in Fig. 1 was used for the anaerobic collection and storage of 10 to 15 ml. specimens of blood "under mercury." It is compact, portable, and stands firmly on its own base. It has proved satisfactory in about eight months' use in this laboratory.

In preparation of the vessel for use, the lower expanded part of the outer bulb, the storage chamber (inner bulb), and the capillary and cup above it are filled with mercury. A piece of ⅛ by 3/32 inch rubber tubing (not shown) is attached to the nipple in the cup and extends about 2 cm. above its rim. Liquid anticoagulant in a graduated 1 ml. pipette inserted in the top of this tube is allowed to flow toward the outer bulb until it passes through the stopcock. Then the stopcock is turned and the desired amount (usually 0.3 ml.) is delivered into the chamber. The rubber tube is removed and the cock is reopened to allow mercury to fill the capillary between cup and chamber. The rubber tube is again attached and filled with mercury from a capillary pipette or syringe.

The blood specimen is taken into a syringe containing oil. The glass tip of the syringe is inserted into the rubber tube. Any minute bubble trapped at this point is rejected through the capillary leading into the outer bulb. The unexposed specimen is allowed to flow into the chamber. When the rubber tube is removed, mercury in the cup immediately seals the top of the capillary. The cock is opened momentarily to allow mercury to flush blood from the capillary into the chamber. Mercury is swirled around the walls of the chamber by gently shaking the vessel in a slanted position in order to mix the blood with anticoagulant, and later to maintain a uniform distribution of red blood cells in the specimen during sampling. To withdraw a sample for analysis, a clean piece of rubber tubing is attached as before. Mercury from the capillary and a drop or two of blood are sucked into any convenient pipette and discarded. The sample is then drawn into a measuring pipette, such as the Van Slyke-Ostwald. The remaining unused specimen is protected by resealing with mercury in the usual manner.

---

*From the Department of Internal Medicine, College of Medicine, University of Cincinnati.

Received for publication, June 1, 1942.

The dimensions of parts of the apparatus, which are not critical, can be obtained by comparison with the scale included in Fig. 1. For best results the capillary and bore of the plug of the cock must be free of offsets, bulges, or

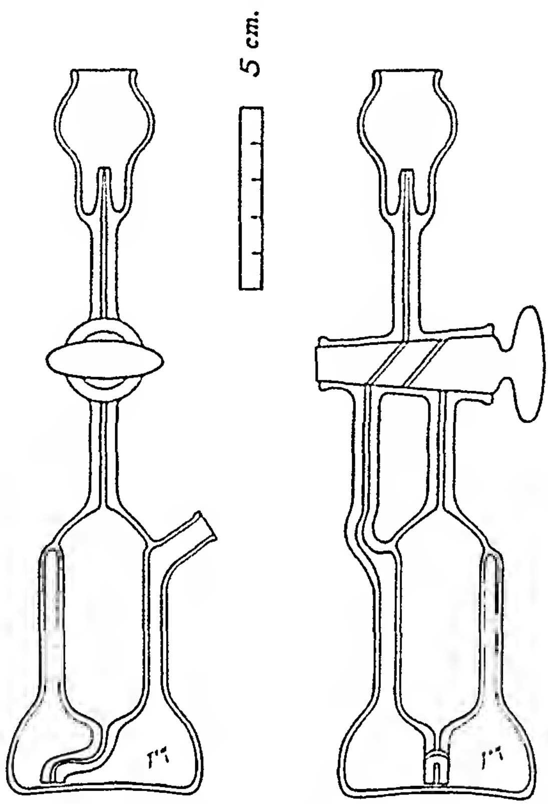

Fig. 1.—Two views of the mercury-sealed blood storage vessel. Left, from the right side. Right, front view.

pockets in which blood can collect, and should be of approximately 0.8 mm. inside diameter. The inside junction of the capillary with the top of the chamber should be abrupt so that the capillary remains filled with mercury during stirring of the specimen.

In Memoriam

ARTHUR H. THOMAS

Few names have been more closely identified with medical laboratories than has that of Arthur H. Thomas whose death occurred on August 31, 1942.

The Thomas catalogue stands on the shelves of nearly all clinical laboratories. It is doubtful whether there is a laboratory in the country which does not have many pieces of diagnostic apparatus manufactured by the Thomas Company. The name Arthur H. Thomas has appeared in the advertising pages of every issue of *The Journal of Laboratory and Clinical Medicine* from Volume 1, Number 1.

A native of Pennsylvania, Mr. Thomas entered the employ of the old Philadelphia firm of James W. Queen and Company, dealers and makers of optical and scientific instruments in 1892. He organized his own company in 1900. Since then, Arthur H. Thomas Company, dealers in laboratory apparatus and reagents, have remained among the leaders in their field.

Mr. Thomas was a Trustee and Director of Bryn Mawr College and a member of the Board of Managers of Haverford College. He was a member of the Board of the Provident Mutual Life Insurance Company.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

TRYPSIN, Method of Assaying Suitable, for Routine Use in Diagnosis of Congenital Pancreatic Deficiency, Andersen, D. H., and Early, M. V. Am. J. Dis. Child. 63: 891, 1942.

The modified Fermi method is carried out as follows:

The substrate is a 7.5 per cent solution of Knox gelatin, obtained from the local grocer. In a 50 c.c. beaker are placed 18.75 Gm. of gelatin. About 40 c.c. of cold distilled water are gradually added, and the mixture is stirred until it is a semiliquid paste free from lumps. This paste is transferred through a small funnel to a 250 c.c. volumetric flask, and the beaker and funnel are washed with about 100 c.c. of water. The flask is heated on a water bath, with occasional shaking until the solution is clear. It is then cooled, made up to volume with water, and replaced on the water bath until the gelatin is entirely melted. The flask is shaken until the contents appear homogeneous. The gelatin is transferred to a stock bottle, and a small amount of thymol is added. When stored in the refrigerator, the substrate can be used for at least six weeks.

The substrate should be left to melt in an incubator at a temperature of 37° C. for approximately one hour before using. Twenty Wassermann tubes are set in a rack in pairs and labeled from 1 to 10; 2 c.c. of melted substrate are placed in each with a transfer pipette. One cubic centimeter of duodenal juice is placed in a 10 c.c. volumetric flask and made up to volume with a 5 per cent solution of sodium bicarbonate, this giving a 1:10 dilution. One cubic centimeter of this material is placed in a second 10 c.c. flask and made up to volume in the same way, with a resulting 1:100 dilution. Each of the first pair of tubes then receives 0.125 c.c. of the 1:100 dilution, measured with a 1 c.c. Mohr graduated pipette, and 1.875 c.c. of 5 per cent sodium bicarbonate solution: this makes a total volume of 4 c.c. in each tube, of which 0.00125 c.c. is duodenal juice. The remaining tubes are set up in a similar manner; the second pair each receives 0.25 c.c. of 1:100 dilution, and the following ones 0.5 and 1.0 c.c. of the 1:100 dilution; then 0.2, 0.4, 0.8, and 1.6 c.c. of the 1:10 dilution; and finally 0.32 c.c. of the undiluted juice in a total volume of 4 c.c. The remaining pair of tubes contains no juice and serves as a control. Each of the tubes is then covered by the thumb and inverted several times to insure mixing, care being taken to handle the control tubes first, then the pair with the lowest concentration of juice, and so on in order. The rack of tubes is incubated for one hour at 37° C. and is then left in a refrigerator at about 4° C. Twenty to twenty-four hours later the tubes are removed from the refrigerator and read immediately. The lowest dilution in which the gelatin has liquefied in one or both tubes is considered as the reading.

PNEUMONIA, Recognition of Virus Type, Goodrich, B. E., and Bradford, H. A. Am. J. M. Sc. 204: 163, 1942.

Virus-type pneumonia presents specific clinical features permitting diagnosis by positive findings. Diagnosis by exclusion alone is seldom necessary.

Chemotherapy with the sulfonamide group of drugs is not indicated in this disease. Recognition of this disease may avoid needless and possibly dangerous therapeutic efforts.

The initial roentgenographic appearance may closely simulate acute exudative tuberculosis. Progress roentgenographic study may be necessary for differentiation.

There is evidence that this disease is now showing an increasing incidence. This fact is explained not alone by familiarity with the clinical concept.

TUBERCLE BACILLUS, A New Method of Staining, Weiss, E. Am. Rev. Tuberc. 42: 199, 1942.

1. Mordant: The mordant consists of two separate solutions. Solution A contains 100 Gm. of tannic acid dissolved in 100 c.c. of 95 per cent alcohol. Solution B contains 15 c.c. of glacial acetic acid diluted to 100 c.c. with 15 per cent dilution of "solution formaldehyde" (Merck). Before using the mordant, one part of solution A and two parts of solution B are mixed together. This mixture does not require filtering and keeps for several weeks. Solutions A and B keep indefinitely.

2. Safranine (or pyronine) stain: Two and one-half grams of safranine or pyronine are dissolved in 100 c.c. of 10 per cent alcohol. The dissolving process is facilitated by the application of heat. The solutions are then filtered and keep indefinitely.

3. Decolorizer: Fifteen cubic centimeter of glacial acetic acid are diluted to 100 c.c. with acetone. This decolorizer keeps very well.

4. Löffler's methylene blue: Thirty cubic centimeters of a saturated alcoholic solution of methylene blue (5 Gm. dissolved in 100 c.c. of 95 per cent alcohol) are diluted with 100 c.c. of a 1:10,000 solution of potassium hydroxide. The filtrate keeps well.

Staining Technique.—(1) Prepare uniformly thin smears and fix the dry smears over the flame. (2) Cover the slides with the foregoing mordant mixture and steam for five minutes. (3) Wash with running water. (4) Cover the smears with the above safranine or pyronine stain and steam for five minutes. (5) Wash with running water. (6) Decolorize the slides with the above decolorizer until they become colorless. (7) Wash vigorously with running warm water. (8) Cover the smears with Löffler's methylene blue for one minute. (9) Wash with running water and allow the slides to dry. The tubercle bacilli appear as large, thick, deeply red-stained rods while the other bacteria and tissue structures are stained blue.

Evaluation of the procedure: The proposed method has been compared with the Ziehl-Neelsen method on at least 250 diagnostic smears. The tubercle bacilli appeared not only thicker and larger but also more numerous. These observations are based on actual counts performed on the above specimens.

ALKAPTONURIA, The Instantaneous Diagnosis of, on a Single Drop of Urine, Fishberg, E. H. J. A. M. A. 119: 882, 1942.

The urine is made strongly alkaline with sodium or potassium hydroxide and dropped on regulation sensitized photographic paper. Wherever a drop of the urine touches the paper, the latter turns coal black instantly, a process similar to that used in everyday photography. This may be done in full daylight.

No other substance present in urine, either normally or pathologically, is capable of reducing the photographic paper in this manner. Diabetic urine, no matter how high the concentration of reducing sugar, remains without effect. Also, the higher concentrations of vitamin C present in urine after metabolic experiments do not act in this manner.

Since alkaptonuria is either total or absent and the substance is excreted in quantities as high as 16 Gm. a day, usually, however, about 3 to 5 Gm., the reaction is unlikely to be negative in an alkaptonuric patient at any time.

ORAL GLUCOSE TOLERANCE TESTS, Instances of Disagreement in the Results of Two Types of, Langner, P. H., and Dewees, E. J. Am. J. M. Sc. 204: 85, 1942.

From a group of 160 subjects who had submitted to the two-dose, one-hour glucose tolerance test, 16 cases are presented in which the results were border line or slightly abnormal. A one-dose test was also performed on these persons. In 13 instances the one-dose test and the available clinical data indicated a normal carbohydrate metabolism and, therefore, were in disagreement with the two-dose glucose tolerance test. The authors believe that the conventional one-dose glucose tolerance test is more reliable than the newer Exton-Rose procedure.

PORTAL CIRRHOSIS, Gottardo, Paul, and Winters, W. L. Am. J. M. Sc. 204: 205, 1942.

A series of 24 cases of portal cirrhosis of the liver in varying stages was studied in an attempt to correlate clinical and laboratory findings. The diagnosis was confirmed by peritoneoscopy in 20 cases and by post-mortem examination in 4 cases. Marked change in the serum albumin and globulin were noted in 100 per cent of the cases. There was a marked tendency to the lowering of the serum albumin and a rise of the serum globulin, with a consequent lowering of the albumin globulin ratio in all cases. There was a reversal of the albumin-globulin ratio in two-thirds of the cases. Jaundice was a fairly constant feature, being present in some degree, as measured by the icteric index, in all cases. Jaundice was evident on physical examination in 79 per cent of the cases. Changes in the peripheral blood were marked in 96 per cent of the cases. A macrocytic or hyperchromic anemia was present in 67 per cent of the cases while 25 per cent exhibited a microcytic or hypochromic anemia. One case presented a typical severe sickle-cell anemia. Deficiency of liver function, as determined mainly by the hippuric acid test and also by a glucose tolerance and a bromsulfalein test, was noted in 83 per cent of the cases. When the serum protein determinations were utilized as a liver function test, 100 per cent of the cases exhibited a diminution of liver function.

A correlation of clinical and laboratory findings, together with peritoneoscopic examination of the liver and post-mortem analysis, would appear to offer useful fields of investigation in liver disease.

RENAL GLYCOSURIA, The Renal Blood Flow, Glomerular Filtration Rate and Degree of Tubular Reabsorption of Glucose in, Friedman, M., Selzer, A., Sugarman, J., and Sokolow, M. Am. J. M. Sc. 204: 22, 1942.

The effective renal blood flow (diodrast clearance) and the rate of glomerular filtration and the degree of renal tubular reabsorption of glucose were studied in 7 normal persons, and in 5 patients with renal glycosuria.

The effective renal blood flow and glomerular filtration in the patient with renal glycosuria were found to be normal.

The lessened tubular reabsorption of glucose in the person with renal glycosuria does not appear to be due to an organic kidney defect, for at plasma glucose levels above 200 mg. per 100 c.c. the efficiency of tubular reabsorption of glucose in these cases equals or exceeds that found in nonglycosuric patients.

GALACTOSE TOLERANCE, Studies on, With Special Reference to Thyroid Disease, Rosenkrantz, J. A., Bruger, M., and Lockhart, A. J. Am. J. M. Sc. 204: 35, 1942.

The factor of age per se appears to exert little or no influence on the galactose tolerance curve.

Patients with hyperthyroidism, Bright's disease, upper respiratory infections, malignant disease, and those who have recently received sulfonamide therapy frequently demonstrate impairment in galactose tolerance following the oral administration of this sugar. The impairment in galactose tolerance, however, is most marked in patients with thyrotoxicosis, which may be ascribed to a dual mechanism: (a) increased rate of absorption of this sugar from the intestinal tract and (b) hepatic damage.

Patients with diabetes mellitus are shown to have a normal tolerance for ingested galactose.

PROGRESS

ANTIBODY PRODUCTION AND THE ANAMNESTIC REACTION*

Paul R. Cannon, M.D., Chicago, Ill.

Some important aspects of antibody production have remained obscure for many years because of the doubt concerning the chemical nature of antibodies. The problem of antibody action, therefore, has received more attention than has that of antibody structure. Within the past few years, however, new facts about the chemical constitution of antibodies have suggested new methods of approach to the general problem of antibody formation. The resultant rapidly changing viewpoint can be briefly summarized as follows: In 1929 Wells,[1] in expressing the commonly held opinion of that time, said, "We have absolutely no knowledge what these antibodies may be, or even that they exist as material objects. Like the enzymes, we recognize them by what they do without knowing just what they are. We do not know whether they are specific molecular aggregates or merely physical forces dependent on altered surface energy of the same substances which were already present in the blood before the process of immunization was even begun." Zinsser, two years later, indicated a changing point of view:[2] "It is generally assumed that antibodies cannot be separated from proteins and are usually contained in the pseudoglobulin fraction, in some cases in the euglobulin fractions of the sera." By 1938 Heidelberger had stated the current view in these words:[3] "Although writers on immunology are still to be found who prefer to consider antibodies as ideas, rather than chemical substances, there is now much evidence that antibodies actually are modified serum globulins." And Marrack has recently said (1942):[4] "Now, however, that a large volume of evidence has accumulated which shows that antibodies are modified serum globulins, the chief problem has become the structure and properties of proteins in general and the special characteristics of antibodies in particular." With the chemical composition of antibodies thus definitely established

*From the Department of Pathology, the University of Chicago.

Some of the work on which this discussion is based was aided by the Douglas Smith Foundation for Medical Research of the University of Chicago and the John and Mary R. Markle Foundation.

it should now be possible to proceed more confidently to the study of the conditions that influence their production.

Present-day theories regarding the formation of antibodies all agree in postulating their intracellular production from globulin. The molecules of globulin are synthesized in stereochemical relationship to antigen, and when released, exhibit specific affinities for this antigen. The theory of Breinl and Haurowitz[5] assumes that during the process of antibody formation antigens enter into the mixture of amino acids and peptides and induce new groupings. The formation of antibody thus represents the synthesis of a special kind of globulin in which the molecules orient themselves in ways characteristic for each antigen. As the antibodies pass into the blood the antigen remains behind, thereby continuing to influence the formation of new antibody globulin until the antigenic components are destroyed or eliminated from the antibody-producing cells. Alexander[6] postulates the development within cells of "new specific catalysts" capable of directing antibody synthesis. During their development the antigen becomes an "essential part of the directive surface of the catalyst particles, thereby leading to the formation of groups of particles with reversed electrostatic charge patterns." By such a mechanism minute quantities of antigen, even as little as one molecule, can "convert a cell or an extracellular catalyst into a potential producer of antibody." Mudd's theory[7] embodies the idea that antibodies are synthesized from peptides and amino acids in an "orienting environment, namely, the antigen-protoplasm interface." Amino acids which become coupled to the growing antibody molecule must conform to the "spatial and chemical requirements of the interface in which synthesis is proceeding." Therefore, the antibody corresponds structurally to the configurations of the antigenic surface and hence is specific, i.e., after dissociation it can recombine with antigenic molecules of similar structure. Furthermore, after dissociation the antigen again is available to act as a directive pattern for further synthesis of antibody. Pauling[8] has suggested recently that during antibody formation the molecules of antigen act as directive patterns or templates in the process of globulin synthesis; consequently, a molecule of antibody differs from a molecule of normal globulin only in the portion of the coiled polypeptide chain which has been "templated" during synthesis by contact with portions of the antigen. According to this concept normal globulin and antibody globulin are essentially identical chemically but differ structurally somewhat as one automobile tire may differ from another in tread pattern although being chemically similar. Further verification of this concept is suggested by the recent experiments of Pauling and Campbell,[9, 10] demonstrating the formation of specific antibodies in the test tube by a process of "unfolding" of polypeptide chains, followed by a "refolding" in the presence of antigen. Later dissociation of the complex releases the antibody globulin molecules which can then recombine with their specific antigen.

Inasmuch as these theories and the facts on which they are based all warrant the conclusion that antibody globulin is specifically modified normal globulin, it becomes evident that the mechanism of antibody formation is closely related to that of globulin production. Furthermore, if both types of globulin arise from the same source, deficiencies in the formation of the one must be related to deficiencies in the production of the other. It would seem, therefore, that a clearer understanding of the conditions determining the production of

globulins should help to elucidate both the nature of the antibody mechanism and the processes of antibody production.

Much progress has been made in recent years in the search for the origin of the serum proteins, and many workers have emphasized the importance of the liver; but, as has been pointed out,[11] contradictory experimental results make it impossible to conclude that the liver is the sole source. Reimann, Medes, and Fisher, in their review of the subject,[11] remarked: "It would, however, seem reasonable to search for the site of origin of blood proteins in the blood-forming organs and, for this reason, the bone marrow, the endothelial system including the liver and spleen, and the cellular elements of the blood have been widely studied. Since it is now generally accepted that bilirubin arises from hemoglobin after the dissolution of erythrocytes, it seems plausible to suggest that the plasma proteins might arise in a similar manner from certain cells in the circulation or in the bone marrow, or from tissue cells generally. It would be in the nature of biologic economy to utilize the substances thus liberated, and certain experimental and presumptive evidence supports this view."

Evidence substantiating this suggestion of Reimann, Medes, and Fisher has come both from observation and experiment. Thus Downey and Weidenreich[12] observed the shedding and dissolution of protoplasmic material from lymphocytes and plasma cells and thought that this might indicate a secretory activity of these cells. Sabin[13] reasoned from her earlier studies on the origin of the blood vessels in the chick blastoderm that "since for a vessel to function as such it is essential for the plasma to contain some protein to maintain the balance of intra- and extracellular fluid, the original transformation of a solid mass of angioblasts into a vessel involves the sacrifice of some cytoplasm to make the serum proteins." Her later experiments utilized "marked antigen" of alum-precipitated dye protein, the fate of which, when it was injected into rabbits, could be seen within macrophages. She observed that "coincident with the time when the dye protein is no longer visible within the cells and when there are antibodies in the serum, there is a marked shedding of the surface films of the macrophages without damage to them." If this process of cytoplasmic shedding is a general property of globulin-producing cells, any such cell which can phagocytose antigen or allow its entrance into the cytoplasm may be a precursor of antibody; furthermore, a part of the antibody globulin may remain within the cell for long periods of time instead of being "sacrificed" as blood protein to the surrounding fluids. Landsteiner and Parker[14] have shown, in tissue culture, that in the fluids resulting from the growth of connective tissue cells of chicks in rabbit plasma, proteins are formed which react by precipitin tests with sera from rabbits injected with chicken serum. No attempts were made to determine whether the proteins were albumins or globulins, but the experiments furnished presumptive evidence that connective tissue cells can form serum proteins. It would be of particular interest to know to what extent such cells can produce globulins; their inability to do so adequately and continuously under the artificial conditions of tissue culture might explain the numerous conflicting results of attempts to produce antibodies in vitro.

The idea of the intracellular origin of globulin becomes especially important in connection with the possibility that immune reactions may occur independently of the presence of antibodies in the blood. Besredka,[15] in his formu-

lation of the concept of local immunity, postulated a local tissue immunity without the obligatory participation of antibodies in the circulating fluids. Kahn[16] suggested that specifically immunized tissues may acquire a capacity for union with antigen independent of the presence of antibodies in the blood serum. Seegal and Seegal[17] demonstrated antibodies in ocular tissues in the absence of demonstrable antibodies in the adjacent extracellular fluids. Dienes and Mallory[18] pointed out that hypersensitiveness of the tuberculin type may occur independently of the presence of humoral antibodies and concluded that "if circulating antibodies are involved in the mechanism of this type of hypersensitivity they must be of an unknown nature or else exist in the blood stream in some as yet undetectable form. It appears more probable that we are dealing with an altered tissue reactivity." Walsh and Cannon[19, 20] concluded that regional immunization may lead to the formation or accumulation of antibodies in locally immunized tissues in concentrations higher than in other organs of the same animal and at times even higher than in the blood serum. Although the above workers have all used methods which are admittedly inadequate in some respects, sufficient evidence exists, nevertheless, to indicate the presence of changed reaction capacities of tissues which do not parallel the antibody content of the blood. Inasmuch as the solution of many of the problems of allergy and of tissue immunity depends upon the understanding of the relative influences of cellular and humoral immune reactions, continued efforts must be made to determine their respective potentialities.

An immune phenomenon hitherto not adequately studied is the anamnestic reaction. This phenomenon, while generally recognized as a source of error in the interpretation of certain laboratory procedures, has not received the theoretical attention it deserves. The name "anamnestische serum reaktion" resulted from observations by Conradi and Bieling[21] in 1916 that soldiers previously vaccinated with the typhoid vaccine had a sharp rise in titers in the Gruber-Widal reactions in the course of febrile diseases that stimulated typhoid fever, but that later proved to be something else, as for example, typhus, miliary tuberculosis, pneumonia, erysipelas, bacillary dysentery, Weil's disease, etc. Conradi and Bieling demonstrated in rabbits immunized against typhoid bacilli that the later injection of colon, diphtheria, or dysentery bacilli also caused a sharp rise in the titer of the serum against typhoid bacilli. They concluded, therefore, that the stimulation of antibody-producing cells by heterologous microorganisms caused them to "recall" their previous production of antibodies to typhoid bacilli.

These observations of Conradi and Bieling, although not new, served to emphasize the significance of earlier ones. Dieudonné,[22] for example, as early as 1906 had shown that the injection of sodium cinnamic acid into typhoid-immunized rabbits with low agglutinative titers caused a renewed formation of agglutinins. This demonstration apparently aroused but little interest until the diagnostic problems arising in World War I called renewed attention to the importance of the anamnestic reaction. Thus, Fleckseder[23] in 1916 concluded that many kinds of febrile diseases could cause a sharp rise in the concentration of agglutinins to the typhoid bacillus in the serum of immunized persons, and Weil and Felix[24] saw a rise in titers in the Gruber-Widal reaction in approximately 53 per cent of patients in the course of typhus, as well as to some degree

in other infectious processes. In 1917 Dreyer and Inman[25] emphasized the importance of quantitative methods in agglutination tests in typhoid-immunized persons with enteric disease because of the concomitant production of major and minor agglutinins. In the same year Baehr[26] said: "It has been occasionally noted that the Widal reaction may become positive during any febrile disorder in persons who previously had typhoid fever or who have recently been vaccinated with typhoid bacilli. . . This temporary lighting up of the Widal reaction during typhus fever was commonly observed by the German and Austro-Hungarian army bacteriologists in Russian Poland and Volhynia, for all the troops had received typhoid vaccinations." It was not known until many years later that the capacity to produce agglutinins to the typhoid bacillus after immunization may persist in healthy persons for as long as from six to nine years.[27]

The demonstration by Dieudonné that nonspecific agents can elicit the anamnestic response was confirmed in 1917 by Kirstein[28] in his experiments showing that infection of typhoid-immunized rabbits with vaccinia virus also caused a mobilization of agglutinins to the typhoid bacillus. He emphasized particularly the fact that nonbacterial agents had a stimulative effect. In all of these earlier observations, however, the primary emphasis was on the practical aspects of the reaction because of the diagnostic difficulties presented, and only a few efforts were made to ascertain the cause of the anamnesis. Some attributed the reaction to the reappearance of "preformed antibodies";[26] others thought that the acute hyperplasia of the spleen was responsible; only Conradi and Bieling made any attempt to determine experimentally the underlying nature of the phenomenon.

The anamnestic phenomenon can be demonstrated, also, against nonbacterial antigens. Obermeyer and Pick[29] in 1904 observed the reappearance of precipitins to beef serum after injection of horse albumoses in rabbits previously injected with beef serum. Little attention was paid to this aspect, however, until 1917, when Hektoen[30] pointed out an important source of error in the production of precipitins for foreign sera in that, when rabbits were injected with one type of serum and were later injected with a heterologous serum, precipitins to the first serum reappeared. He said at that time: "The particular point on which special stress is placed now is the capacity of the rabbit under suitable conditions . . . to elaborate different precipitins at the same time. It appears that the precipitin production induced in the usual way leaves behind it an increased power of further production so that large amounts of major as well as group and minor precipitins are elaborated on the injection of a new serum or blood. Manifestly, the phenomenon is an expression of an increased reactivity and may be classed with other manifestations of allergy." Bieling,[31] in later experiments, re-emphasized the idea that the changed reaction capacity of tissues is an expression of allergy whereby the power of a cell to produce antibody can be changed both specifically and *nonspecifically*. He visualized the immune state in a cell as a process of development of a nonspecific hypersusceptibility to other kinds of stimuli: as a result of this, later stimuli can engender the appearance of nonspecific antibodies in the pretreated animal. Mackenzie and Frühbauer[32] reported that after precipitins to foreign proteins had disappeared from the blood, later injection of another protein caused them to

reappear; furthermore, the precipitins to the last antigen previously injected were the first to reappear. Hektoen and Welker[33] have shown, also, that subsequent to the induction and disappearance of multiple precipitin formation by the successive introduction of *different* antigens, the injection of only one of the antigens previously used may cause the reappearance of precipitins to the same as well as the other antigens.

During the entire period of study of the anamnestic reaction, unnecessary confusion has centered around the use of the term itself. The word "anamnesis" means "a recalling," and in the anamnestic reaction the antibody-producing cells presumably "recall" or "remember" a previous antigenic experience during the course of a subsequent and frequently unrelated type of cellular stimulation. Because of the heterologous nature of the later stimulus too sharp a restriction has been placed upon this feature of the phenomenon. As Topley[34] has said: "In this connection we note the terminological confusion which has sometimes arisen in the literature. The production, in response to an antigenic stimulus, of an antibody that has been produced in the tissues on some previous occasion is often referred to as an anamnestic reaction (anamnesis recollection). Sometimes this term is used in connection with the type of nonspecific stimulus to which we have just referred—the tissues are stimulated to general activity, in which is included the renewed production of a particular antibody that has been formed at some time in the past. Sometimes, perhaps more accurately, it is employed in reference only to those instances in which the particular chemical stimulus concerned formed part of the earlier experience of the antibody-producing cells." There can be no doubt, therefore, that Topley applies the term "anamnestic reaction" both to the nonspecific and the specific liberation of antibodies into the blood stream consequent to a later antigenic stimulation. This broader point of view implies, therefore, that if antibody-producing cells are to manifest some type of "recollection" of an earlier antigenic experience, there is no reason why this should happen only after a nonspecific stimulation. The determining feature of the anamnestic reaction is the speedy release of antibodies from their site of production, regardless of the stimulus which may bring it about. Acceptance of this point of view makes it immaterial whether the reaction is called "anamnestic," "secondary immune response," "injection de rappel," or the reaction to "stimulating," "booster," or "repeat" injections.

In the present discussion the anamnestic reaction is considered to be the result either of nonspecific or specific stimulation of antibody-producing cells which have undergone earlier antigenic stimulation. After nonspecific stimulation there is the reappearance of antibodies to the earlier antigen; after specific stimulation there is an earlier and more abundant reappearance of antibodies to the specific antigenic stimulant.

The importance of the anamnestic phenomenon is seen also in infectious processes. For example, the use which is now being made of the so-called "stimulating" or "booster" injections of toxoids in order to call forth an accelerated liberation of antitoxins[35-38] is an instance of "specific anamnesis," whereby higher levels of antitoxic immunity are attained in children and in soldiers who have been immunized previously with toxoids of diphtheria and tetanus. Jones and Moss describe the case of a person who eight months after immunization with tetanus toxoid suffered a puncture wound of the hand.

His blood serum, when tested after immunization, had shown the following antitoxic levels: at six weeks, one-tenth unit per cubic centimeter; at twelve weeks, one-twentieth unit; at six months, one-fortieth unit. On the day following the injury he was reinjected with 0.25 c.c. of alum-precipitated tetanus toxoid; his blood serum, tested one week later, contained one-tenth unit per cubic centimeter, and four weeks later, one-half unit. The authors estimated that his total blood, therefore, would have contained approximately 3,000 units of antitoxin, or "more than enough antitoxin to protect against the development of clinical tetanus" as well as to possess an active immunity far superior to the passive protection which would have been possible by the injection of antitoxin. These authors showed later, moreover, that stimulating injections of toxoid not only accomplished the accelerated elevation of antitoxic levels in the blood, but that these levels persisted longer than after first injections. It is not unlikely that in persons adequately immunized with toxoids a later infection with diphtheria or tetanus bacilli will, because of the speedy liberation of small quantities of toxin into the tissues, engender an accelerated secondary response and thus bring freshly liberated antitoxins quickly to the site of developing infection, thereby favoring an early termination of the infective focus.

The anamnestic reaction may operate similarly in infections in which antigenic stimulations accompanying the acute infectious process may liberate, in varying degrees, antibodies engendered by earlier antigenic experiences. It is conceivable that such a response would help materially in restraining the development of incipient secondary infections which might otherwise complicate seriously the major infectious process. For example, Hektoen and Boor[39] called attention to the fact that "the serum of apparently healthy persons contains, as is well known, small quantities of a great variety of antibodies for infectious, as well as non-infectious, antigens . . . it seems reasonable to assume that 'normal antibodies' may develop in response to antigens that enter the blood from the digestive and respiratory tracts, as well as in other ways."

It may be recalled that during the first World War the most serious complications of influenza and measles occurred in soldiers from the sparsely settled rural areas. These men, presumably, had had fewer antigenic experiences with microorganisms commonly implicated in respiratory infections than had soldiers coming from the thickly populated urban areas. It is possible that, during the course of influenza or measles, the anamnestic mobilization of multiple antibodies to various types of streptococci and pneumococci may have played an important part in restricting the early growth and spread of secondary bacterial invaders which might otherwise have caused serious or even lethal infections.

The anamnestic reaction may also play a beneficial role in the treatment of chronic or focal infections in which, presumably, foci of infective agents persist in the tissues over long periods of time. For example, in the treatment of chronic syphilis, arthritis, or iritis, stimulation of the antibody mechanism by various foreign protein materials, such as typhoid vaccine, milk, malarial parasites, or by hyperthermic means, may cause the liberation into the blood stream of significant amounts of specific antibodies engendered by previous antigenic experiences but which could not otherwise gain access to the infected foci. According to Cecil,[40] "perhaps the most important function of the foreign protein reaction is the mobilization of immune bodies in the circulating blood. . . . Indeed, it has

been shown by numerous authors that any form of fever is conducive to an increase of immune bodies in the circulating blood. Whether this is due to an increased formation or to increased mobilization of antibodies it is difficult to say." O'Leary[41] also remarks: "The literature contains numerous hypotheses as to the mechanism that produces the satisfactory results of fever therapy, but not one of these offers sufficient evidence to warrant its acceptance except as a theory. In the fever induced by the malarial treatment, as well as in that produced by other nonspecific agents, it is my impression that the satisfactory therapeutic effects are the result of some fundamental change in the immunologic processes, the nature of which is unfamiliar. The high temperatures which are produced may be a factor in bringing about these changes." Although more examples might be cited, these will suffice to illustrate the general importance of the phenomenon, not only through its effects upon various laboratory procedures, but also upon many important problems of acquired resistance.

Perhaps, however, the relationship of the anamnestic reaction to the problem of antibody production is of even greater significance. Although it is now generally agreed that the antibody-producing mechanism consists predominantly of macrophages comprising the reticulo-endothelial system, it is possible that antibody formation may be more widespread. In fact, any cell which can actively phagocytose foreign antigenic materials, or even allow them to enter its cytoplasm and remain there while globulin is being synthesized may, presumably, either produce antibody for release into the circulating fluids or develop a changed reaction capacity to the same type of antigen. It seems probable, therefore, that several kinds of cells may play an important part in the synthesis of globulin and that tissue globulin functions as the mother substance or matrix from which antibodies are formed, regardless of whether they are liberated into the blood or remain at their sites of formation.

Such a matrix of globulin, if it is to function effectively both for the production of antibodies and for the preservation of the antibody mechanism itself, must be adequate qualitatively and quantitatively. Consequently, the reserves of tissue globulin must have been properly constructed during synthesis, and in sufficient amounts. Inasmuch as these arise ultimately from amino acids in the food, nutritional conditions suitable for the effective synthesis of globulin are necessary. This particular aspect of the problem will not be discussed in the present paper, since it has been considered in more detail elsewhere.[42] It is a well-known fact, however, that the production of antibodies is, as a rule, poorer in conditions of immaturity, severe malnutrition, and excessive loss of blood proteins. While the causes of this impaired capacity to form antibodies are still unknown, antibody-producing cells possessing an adequate content of tissue globulin of good quality should be capable of synthesizing as many varieties of specific antibodies as there are antigenic templates to influence their specific formation. Hektoen and Boor[39] have shown that the injection of 35 different antigens at one time engendered the simultaneous formation of 34 specific antibodies. Furthermore, Delves[43] found that the immunization of rabbits with a mixture of ten kinds of laked blood led to the simultaneous production of specific precipitins for many blood proteins and specific agglutinins and lysins for different species of blood corpuscles. These findings indicate that, under normal conditions of antibody formation, antibody synthesis depends upon

the presence within the antibody-producing cells of antigenic components, regardless of their numbers at any one time. The process may be likened to that of the printing of letters of dough for the preparation of "alphabet soup." If one compares the dough to tissue globulin, one can think of it as passing through a stamping machine with the various letters of the alphabet emerging. If, however, some of the letter molds become injured or lost, the letters will come out poorly marked or not marked at all. Furthermore, if the supply of dough runs low or deteriorates in quality because of dilution or other change, letters of poor quality will emerge.

If globulins, whether normal or specifically modified by antigen are products of cells, it becomes essential that the supply of amino acids for proper cellular functioning be constantly maintained. Furthermore, it may be highly important that the intracellular reserves of protein materials be maintained in these or in other cells of the body in order that globulin synthesis may go on uninterruptedly and even at an accelerated tempo in the presence of infection. Whipple and his collaborators[44] have shown that protein materials, particularly in the liver, constitute an important reservoir of readily mobilizable protein aggregates which are in dynamic equilibrium with the blood proteins and which can be called upon in time of need for the nourishment of the protein-depleted tissues. Schoenheimer and his associates[45] have shown also that the process of interchange of amino acids within the tissues is extremely dynamic, and that, if during the process of antibody synthesis, an amino acid (glycine) containing isotopic nitrogen is fed to a rabbit, some of the heavy nitrogen quickly appears in the antibody globulin itself. It is evident, therefore, that even during the period of antibody formation amino acids in the food may play an active part in the construction of antibody molecules.

This evidence of the active participation of amino acids of the food in antibody production re-emphasizes the problem of protein metabolism during infection. The loss of body protein during infectious disease, due to the fever, the toxemia, and the insufficient regeneration because of inadequate food intake, may be an important factor in the depletion of the protein reserves. For example, patients with typhoid fever may lose as much as 100 Gm. of body nitrogen in from eight to twelve days; the outstanding clinical fact in such patients is starvation. One may wonder in retrospect about the consequences of the low-calorie diets in the treatment of typhoid fever, particularly during those stages of the disease in which the tissues, presumably, needed an adequate supply of immune substances. It may be that the not infrequent relapses of those times were caused, in part, by the scarcity of amino acids essential for the continued production of antibodies; and perhaps the favorable effects of the Coleman-Shaffer high-calorie diet,[46] with its correspondingly higher content of amino acids, were due in some degree, to the better production of antibodies as well as to the greater calorie values and the protein-sparing effects of the carbohydrate. Coleman[47] has said concerning prognosis in typhoid fever that "when a patient is well nourished, the natural history of the disease is profoundly modified in many respects. There is evidence that complications occur less frequently. Such complications as do occur are less serious in their consequences. The immunity processes appear to be favorably influenced." He states, furthermore, that from his observations "the mortality rates in patients who were well

nourished were from 50 per cent to 75 per cent lower than in those who were partially starved." These observations suggest that in other subacute and chronic infectious diseases, as for example, tuberculosis, syphilis, malaria, rheumatic disease, etc., good nutrition may also facilitate recovery to a considerable degree by its action in promoting the more effective synthesis of antibody globulin.

The probability that the antibody mechanism is affected by starvation is of particular importance today as one of the problems of war. The association of war, famine, and pestilence has long been known, but the reasons for the rise of epidemics and the higher death rates from infection are still not well understood. During World War I the incidence of tuberculosis rose greatly in Germany and elsewhere, and it has been estimated that at least 800,000 persons died as a result of the food blockade, many because of infectious diseases. Part of this high death rate has been attributed to the lowered intake of protein in the diet. The possibility that depleted protein reserves may reduce the capacity of a starving person to produce antibody-globulin quickly and effectively may be of profound importance in any incipient infection which might otherwise be readily terminated. Experiments now in progress indicate very definitely that rabbits with hypoproteinemia, the result of plasmapheresis and a low protein diet, show an impaired ability to form antibodies. Such experiments suggest the tremendous importance of maintaining adequate protein reserves; the only way, obviously, is by the ingestion of sufficient amounts of protein in the diet.

The question whether there are reserves of stored protein in the tissues comparable to those of glycogen and fat is controversial, although there is but little doubt that under some conditions, as after hemorrhage or plasmapheresis and during other hypoproteinemic states, organs and tissues may contribute proteins to the blood. Nor is it known in what form or where the protein reserves are stored, although the liver undoubtedly plays an important and perhaps a predominant role. Berg[48] claimed many years ago that in well-nourished animals protein deposits could be demonstrated microscopically in the liver cells as intracellular "protein inclusions"; in starving animals these inclusions disappeared and the cells became smaller. Furthermore, Berg and Cahn-Bronner[49] showed that, when starved animals (salamanders and rabbits) were fed a mixture of amino acids obtained from enzymatic hydrolysis of beef flesh, these inclusions reappeared in the liver cells within a few hours and were indistinguishable from those seen after ordinary protein feeding. They concluded, therefore, that these represented a phase of protein storage. Elman and Heifetz[50] showed, furthermore, in dogs kept on a low-protein diet, that as the albumin values of the blood fell, there was a concomitant decrease in the amount of stainable cytoplasm in the hepatic cells. The latter became more vacuolated and the water content of the liver as a whole increased.

There is no conclusive evidence as yet, however, as to the chemical state in which protein is stored in the liver. Luck[51] maintained two groups of rats on high- and low-protein diets, respectively, and analyzed the livers quantitatively for evidence of protein storage. He found that in the high-protein group there was an increased amount of protein per unit weight of tissue but that all the protein fractions were increased about proportionally when compared with the

similar fractions in the low-protein group. Addis and his associates,[52] in quantitative studies on the effects of fasting in rats upon protein storage, found that the liver in seven days lost about 40 per cent of its total protein, thus indicating, also, the importance of this organ as a storehouse or way station in protein metabolism. Whipple and his collaborators have demonstrated by physiologic methods the important part played by stored proteins in the bodily economy as a "reserve against adversity in the sense that it ean be circumspectly depleted without apparent injury to the body." Whipple suggests that intracellular proteins may exist in three forms, viz., labile reserve protein, dispensable reserve protein, and indispensable fixed protein, and that, because of the existence of a dynamic equilibrium between the fluids and the tissues, there is an "easy exchange between the plasma protein and the labile protein stores of the body cells." Under conditions of anemia, plasma depletion, or protein fasting even the dispensable reserve proteins may also be drawn upon to some extent. The indispensable fixed proteins, however, cannot be removed unless the cells are seriously damaged or destroyed. It is of interest, furthermore, that when the "stored" proteins are contributed to the blood stream under the above conditions, the most labile protein reserves seem to be those with larger molecules. Thus Berger[53] has shown that after the injection of a foreign protein into rabbits, the resulting hyperproteinemia occurs primarily (in about four days) as a hyperglobulinemia with an associated hypoalbuminemia. The albumin levels rise later, usually in from sixty to one hundred and twenty days. Similarly, after severe blood loss in normal animals there is an increase in normal globulin in the blood, whereas, in immnnized ones antibody globulin is quickly liberated into the blood, as seen in the anamnestic response after severe hemorrhage.

The facts cited in this brief review of the problem of antibody production and the anamnestic reaction suggest that antigenic components may persist within antibody-producing cells for considerable periods of time after injection or vaccination and thus are able to function as templates when later stimuli cause an acceleration of antibody prodnetion. Furthermore, there is evidence that antigenic templates which were effective earlier in the process of antibody formation tend to disappear or to become changed with time so that they lose their ability to influence specifically the later synthesis of globulin. Further studies of the anamnestic phenomenon should throw more light upon many more important aspects of the general problem of antibody production.

SUMMARY AND CONCLUSIONS

The antibody-producing mechanism comprises a widely distributed system of cells, including macrophages, fibroblasts, and possibly even endothelial cells and to some extent epidermal cells, all of which may have the potentiality in varying degrees of synthesizing globulin. Wherever this material is formed, antigenic "templates" may, if present at the sites of synthesis, so influence the structural pattern of the globulin molecules as to confer specific properties upon them. Some of these molecules may pass into the extracellular fluids as antibodies and remain there for variable periods of time; others may persist within their cells of formation. The persistence of this antibody matrix for months or years may explain both the acquisition of acquired resistance inde-

pendently of any considerable amounts of antibodies in the blood as well as many of the tissue reactivities which are commonly regarded as allergic phenomena. The effectiveness of globulin synthesis, and consequently, of antibody production will be determined by the quality and quantity of globulin reserves continuously available. These, in turn, are dependent ultimately upon an adequate intake of amino acids in the food. Diet, therefore, will determine to a large degree both the effective production of antibody globulin and the potential reserve capacity of the antibody mechanism.

CLINICAL AND EXPERIMENTAL

SARCOIDOSIS (BOECK-BESNIER-SCHAUMANN DISEASE) AS CAUSE OF A PITUITARY SYNDROME*

E. J. Kraus, M.D., Peoria, Ill.

COMPARED with other anatomic lesions, the involvement of the pituitary gland by sarcoidosis represents a rare event. According to a recent review on this disease by Longcope,[1] only six cases of pituitary involvement seem to have been published, all accompanied by diabetes insipidus.

The case represented in this paper differs from previous cases in that the pituitary region showed particular findings which might not have been described yet in this combination.

Today we know that sarcoidosis or Boeck's sarcoid is identical with lupus pernio described by Besnier, and that uveoparotid fever represents only a particular manifestation of the same disease. It is a chronic disease of long duration, usually characterized by a mild, often feverless, course, a tendency to exacerbation and refractory behavior to treatment, and often shows spontaneous recession. The underlying process is a granuloma with a certain resemblance to that of tuberculosis. Sarcoidosis is not identical with tuberculosis, but is often combined with it. The most frequent organs attacked are the lungs, lymph nodes, skin, spleen, liver, and eye; however, not many organs escape being involved by the granuloma. Sarcoidosis with especial involvement of the skeleton has been described erroneously by Jüngling,[2] a German author, as osteitis tuberculosa cystica multiplex.

The granulation tissue in sarcoidosis has no tendency to undergo caseation and is characterized by nodules consisting of epithelioid cells, lymphocytes, and giant cells with peculiar calcified inclusions. These nodules are frequently surrounded by a wall of hyalinized fibrous tissue. They are not prone to coalesce but remain separate though often closely approximated. The etiology of the disease is not known; transmission to animals has not been successful so far. Among the laboratory findings, one of the most significant is hyperglobulinemia.

CASE REPORT

The following case is that of a woman, aged 41 years, a teacher by occupation. Her menstruation began at 15 years of age and continued regularly for two years, the periods lasting three days. Then the menses disappeared without discernible cause, after which she bled from the nose quite regularly for two or three days every month. Prior to her death the epistaxis was so heavy that it had to be stopped at the hospital.

*From the Department of Pathology at St. Francis Hospital, Peoria.

Received for publication, May 20, 1942.

The patient gave a history of previous apical tuberculosis. She was anemic for about ten years. She died shortly after admission, her temperature having risen to 104° F.

The clinical diagnosis was hypochromic anemia, thrombocytopenia, hypoplasia of the genitals, and polyuria.

Fig. 1.—Sagittal section through the skull base, showing the dorsum sellae strikingly high and prominent.

Fig. 2.—Aspect of the cranial base, showing the atrophic pituitary gland lying deep in the sella with the flattened pituitary stalk running over the abnormally high dorsum sellae.

Autopsy.—The body was 149 cm. in length and 46 kg. in weight, proportional in its dimensions. Panniculus adiposus measured 3 cm. over the abdomen, 1 cm. over the external bicipital sulcus, and 3 cm. over the fossa ovalis. The skin was without particular pigmentation. The head hair was brown and thinner than normal; the axillae, were without hair; the pubic hair was blonde, scanty, and downy; and the trunk and extremities were hairless. The breasts were small, flat, and poor in fat tissue; the nipples were not prominent; labia majora and labia minora were small.

The skull measured 17 by 14.5 cm. in diameter and up to 0.4 cm. in thickness, with a circumference of 50.5 cm. Brain and meninges were grossly without particular lesions. The pituitary gland on its cranial surface was excavated and lay deep in the sella; the dorsum sellae was unusually high and bent slightly forward. The pituitary stalk which passed over the prominent edge of the dorsum sellae was lengthened, flattened, and whitish in color (Figs. 1 and 2).

The nasal cavity was filled with coagulated blood. The thyroid was small and atrophic. In the left upper lobe of the lungs there was a deep transverse scar with neighboring bronchiectasis. The left apex contained a slaty indurated area, about 2 cm. in diameter, and two smaller calcified foci. There were fibrous adhesions of the apical pleura. Both lungs were

firmer than normal and had reduced air content; the surface in many parts was rough and showed numerous tiny grayish nodules closely compacted. In the left lower lobe a fine network of scar tissue was found in some places. The lobes of both lungs were fused together by fibrous adhesions. In other parts the pleura showed ecchymoses, as did the epicardium. The myocardium, the heart valves, and the aorta did not reveal essential changes. The bronchopulmonary and tracheobronchial lymph nodes were indurated, anthracotic, and contained a few calcified foci. The mediastinal, abdominal, and retroperitoneal lymph nodes were enlarged, especially the perigastric, peripancreatic, and para-aortal ones, which appeared to be about 2 by 3 cm. in diameter, while the iliac, hypogastric, internal inguinal, and mesenteric lymph nodes were only the size of a bean. They were firm in consistency and permeated by grayish-white nodules the size of millet seeds, the nodules being closely approximated in many places.

The spleen weighed 500 Gm., showed fibrous adhesions, and on its cut surface were many miliary nodules almost indistinguishable from the follicles. The liver, partially covered by fibrous adhesions and weighing 1,700 Gm., was light yellowish-brown in color and indurated, offering the picture of a moderate degree of cirrhosis. The gall bladder was shrunken and contained a cholesterol-pigment calcium stone. The pancreas appeared to be normal. The adrenals were small. The kidneys together weighed 200 Gm. They were firm and light yellow in color.

Fig. 3.—One nodule after decalcification, showing foreign body giant cells surrounding the site of the inclusions.

The uterus was small, measuring 5 by 3 cm. The corpus wall measured up to 0.5 cm. in thickness. The tubes were 11 and 12 cm., respectively, in length and very thin. The ovaries were small and shrunken, the vagina was narrow, measuring 6.5 cm. in circumference.

The femurs, ribs, sternum, and vertebras showed signs of osteoporosis. Two-thirds of the marrow in the femur consisted of light gray-red myeloid tissue while one-third was made up of fat tissue.

Anatomical Diagnosis.—Abnormal height of the dorsum sellae with compression, extension, and atrophy of the pituitary stalk; atrophy of the pituitary gland; hypotrichosis; atrophy of the ovaries, uterus, tubes, and labia pudenda; atrophy of the breasts; atrophy of thyroid and adrenals (hypopituitarism); old tuberculosis of the lung apices with fibrous adhesive pleuritis; circumscribed bronchiectasis of the left lung; peculiar granuloma (?) in all lobes of the lungs, all internal lymph nodes (apparently) and spleen; chronic splenic tumor; cirrhosis of the liver; chronic cholecystitis and cholelithiasis; osteoporosis; hemorrhage in the nasal cavity; ecchymoses in serous membranes; anemia.

Bacteriologic Examination.—Cultures on Löwenstein medium taken from spleen, lymph nodes, and bone marrow for tubercle bacilli were sterile after six weeks' observation. Guinea pigs, rabbits, and chickens inoculated with the same tissues did not show any lesions after days. Guinea pigs inoculated with lymph nodes, spleen, liver, and lung of these 'oned animals showed no pathologic lesions after fifty-three days.

Microscopic Examination.—Lungs. There are numerous miliary nodules of variable appearance. Some consist of epithelioid cells, one or a few giant cells similar to Langhans giant cells, and some round cells; frequently these are all intermingled. Other nodules are larger and contain dark violet inclusions (stained by hematoxylin), spindle, round, or rod shaped. Other nodules contain bodies suggestive of cholesterol crystals. The giant cells are intimately attached to these structures, as is typical of foreign body giant cells (Fig. 3). A number of nodules are surrounded by a thin wall of hyalinized fibrous tissue, while others appear to be fibrous also in the center. There is no tendency to conglomerate, though the nodules frequently appear close together. The final stage is a hyalinized scar containing recent nodules as well as calcified inclusions. These inclusions, which chiefly consist of calcium carbonate and calcium phosphate, also give a positive iron reaction, as shown in Turnbull blue sections. In some parts the alveolar septa are thickened, infiltrated with many lymphocytes, and contain recent as well as older and partially hyalinized nodules.

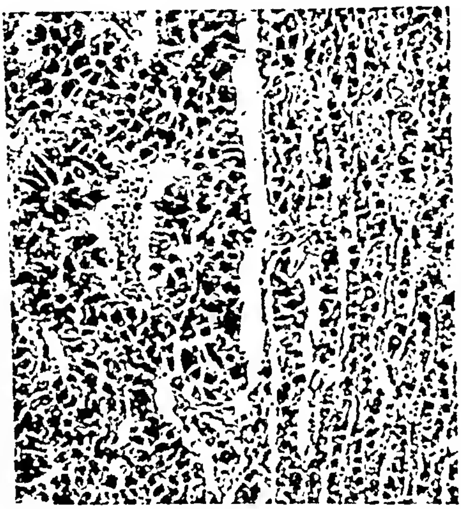

Fig. 4.

Fig. 5.

Fig. 4.—Chromophobe adenoma of the anterior lobe with adjacent parenchyma, showing atrophy by compression.

Fig. 5.—Anterior lobe of the pituitary gland, showing one nodule and fibrous atrophy of the parenchyma.

Lymph Nodes. There are many apparently very recent nodules, together with old lesions. These nodules are small, round, and well-defined accumulations of epithelioid cells with or without lymphocytes, similar to those in tuberculosis. Giant cells are sometimes present. Those with inclusions have darker stained nuclei and cytoplasm than cells withont inclusions. Occasionally inclusions surrounded by a hyaline capsule are seen. In decalcified sections it becomes evident that these calcified inclusions have a particnlar, possibly organic, base which persists after the calcium and iron salts have been dissolved by mineral acids. By fibrosis which starts in the periphery of the nodules in the form of a hyaline shell, the granulation tissue finally passes over into scar tissue.

Liver. The liver shows a moderate degree of cirrhosis with small loose aggregations of epithelioid cells intermingled with a few lymphocytes, sometimes with giant cells, but without the afore-mentioned inclusions. Fat stains reveal a slight, irregular, fatty infiltration.

Spleen. There are microscopically small nodules, variable in appearance, with and without inclusions. There are also calcified inclusions lying free in the pulp. Small ill-defined groups of epithelioid cells apparently represent early stages of the process. The pulp appears slightly fibrotic, and the follicles are rare and atrophic.

Pituitary Gland. Serial sections of the pituitary gland cut in a sagittal plane show a marked excavation of the upper surface. In this region the cell cords of the anterior lobe appear atrophic and run parallel, as is typical of compressed parenchyma of the anterior lobe. However, the pituitary cells in other parts of the anterior lobe also appear atrophic,

being smaller than normal with the chromophilic cells evidently decreased in number. In especially atrophic parts the interstitial fibrous tissue appears thickened and hyalinized. In the middle of the anterior lobe there is a small chromophobe adenoma about 1.5 by 2 mm. in diameter (Fig. 4). The posterior lobe appears particularly small and is almost replaced by tiny nodules with giant cells and calcified inclusions. At the border of both lobes there are a few small colloid-filled follicles. The anterior lobe contains occasional little nodules in the anterior portions of the lobe (Fig. 5). The pituitary stalk is densely infiltrated with small nodules, and only microscopically small parts of the stalk are not destroyed Fig. 6). The capsule of the pituitary gland at the base of the organ is markedly thickened. The infundibulum is likewise infiltrated by tiny nodules, and there are a few on the basal surface of the optic chiasma. The other parts of the floor of the third ventricle were dissected in serial sections, but no essential lesions were found in hematoxylin-eosin stained paraffin section.

Other organs as thyroid, heart muscle, kidneys, and marrow did not show granulomatous lesions in the sections examined.

Fig. 6.—Pituitary stalk infiltrated by granuloma. The black spots represent calcified inclusions.

DISCUSSION

A case of generalized granulomatosis, together with an endocrine disease characterized by genital dystrophia, cessation of the menses, hypotrichosis, and polyuria, has been described. The granulomatosis is characterized by tiny nodules made up of epithelioid cells, lymphocytes, and giant cells differing from those of tuberculosis. These nodules show, in contrast to tubercular ones, that the lymphocytes are frequently intermingled with the epithelioid cells; they do not undergo caseation; they have a particular tendency to get surrounded by a thin hyaline capsule; they have no inclination to coalesce; and they contain peculiar inclusions consisting of an apparently organic base impregnated by calcium and iron salts, while other more rare inclusions seem to be cholesterol crystals. The inclusions give rise to foreign body giant cells, but in addition there are similar looking giant cells which reveal no relation to foreign bodies.

Inclusions, as well as giant cells, may be seen without other components of the granulation tissue, which differs from the findings in any known specific granuloma except the granuloma in sarcoidosis. This granuloma could easily be differentiated from tuberculosis not only by its particular histology as just described but also by negative animal inoculation and cultures.

The involvement of the pituitary and its stalk caused a pituitary disturbance characterized by cessation of menses (substituted, however, by monthly epistaxis), loss of body hair, and polyuria. At autopsy the hypopituitarism manifested itself by atrophy of the ovaries, uterus, tubes, outer genitals, and breasts, and by atrophy of thyroid and adrenals and marked hypotrichosis.

In addition to the destruction of the pituitary stalk and posterior lobe of the pituitary gland by the granuloma, another lesion was found that also might have played a part in the pathogenesis of the hypopituitarism. It was an unusually high and steep dorsum sellae that compressed and stretched the stalk to an abnormal length. How much the chromophobic adenoma in the anterior lobe influenced the picture is hard to say. It might have been compensatory in nature, owing to the atrophy of the anterior lobe, and thus without particular significance as to the development of the pituitary disease.

Since the patient seemed to be normal up to 17 years, with regular menstruation, the anomaly of the dorsum sellae might not have impaired to any great extent the function of the pituitary gland but the damage to the pituitary stalk might have created a "locus minoris resistentiae" where the granuloma easily established itself. On the other hand, the report of diabetes insipidus in other cases of sarcoidosis shows that an involvement of the nervous part of the hypophyseal-diencephalic system is not necessarily based on a previous lesion of this region as described here.

After the granuloma had destroyed the pituitary stalk and the infundibulum, the communication between the pituitary gland and the vegetative centers in the hypothalamus was cut off, the result of which was the atrophy of the anterior lobe. As is known the separation of pituitary gland from the hypothalamus inevitably leads to atrophy of the gland, especially the anterior lobe due apparently to the loss of nerve communications with the vegetative centers in the floor and wall of the third ventricle, and also due to the interruption of channels carrying certain products of the pituitary glands (for instance, gonadotropic hormone) to the diencephalon (Kraus).[3] In view of the long duration of the sarcoidosis it is quite possible that the involvement of the pituitary region by the granuloma reaches far back and that the cessation of the menses might have been the first manifestation of the pituitary disturbance. But it is also possible that the pressure on the pituitary stalk by the anomalous dorsum sellae induced the pituitary disease, which was later much aggravated by the destructive granuloma.

While the disturbance of the water balance certainly resulted from the functional loss of the posterior lobe and pituitary stalk, the genital dystrophia with the hypotrichosis must be referred to the marked atrophy of the anterior lobe.

The atrophy of the thyroid and adrenals also is a result of the pituitary insufficiency as is the generalized atrophy, including the osteoporosis. Since emaciation does not belong to the picture of sarcoidosis, one may suppose that

the generalized atrophy in this case (the patient weighed only 46 kg.) was pituitary in nature.

The vicarious menstruation from the nasal mucosa of many years' duration is hard to explain when one considers the ovaries were entirely atrophic. The later profuse and finally fatal character of the epistaxis might be due to the thrombocytopenia. Since this symptom is not mentioned in other cases of sarcoidosis (while eosinophilia is quite frequent) a causal connection between the sarcoidosis and the blood lesion is not probable, nor is there particular reason to assume pathogenetic relations between the thrombocytopenia and the pituitary disease.

SUMMARY

A case of sarcoidosis (Boeck-Besnier-Schaumann disease) in a woman 41 years of age has been reported. The following microscopic changes have been found characteristic of this granuloma: tiny nodules made up of epithelioid cells, giant cells, and round cells, the latter often intermingled with the epithelioid cells; no tendency to coalesce but rather to be surrounded by a hyaline-fibrous capsule; no tendency to caseation; peculiar inclusions made up of calcium and iron salts compounds deposited in an organic ground substance surrounded by giant cells; occurrence of inclusions, as well as giant cells, alone without other components of the granulation tissue, and finally, conversion into fibrous tissue.

An endocrine syndrome characterized by genital dystrophia, cessation of menses (with vicarious menstruation from the nasal mucosa), hypotrichosis, polyuria, and generalized atrophy has been shown to be caused by the granuloma which has involved the infundibulum, the pituitary stalk, and the pituitary gland itself. An anomaly of the dorsum sellae with pressure on the pituitary stalk probably caused a locus minoris resistentiae for the granuloma. A chromophobe adenoma of the anterior lobe has been interpreted as a compensatory proliferation in an otherwise atrophic organ. A thrombocytopenia causing death could not be referred either to the sarcoidosis or to the endocrine disturbance.

TREATMENT OF CONGESTIVE HEART FAILURE IN AMBULATORY PATIENTS WITH AN ORALLY ADMINISTERED MERCURIAL DIURETIC*

JULIUS BURSTEIN, M.D., GEORGE BROWN, M.D., AND CHARLES KLEIN, M.D.
NEW YORK, N. Y.

IN 1940 Batterman, DeGraff, and Rose reported the satisfactory use of an oral preparation of salyrgan-theophylline† in hospitalized patients suffering from congestive heart failure.[1]

It seemed desirable to test the efficacy of this preparation in the treatment of ambulatory patients with congestive heart failure who ordinarily required the frequent administration of intravenous mercurials for maintenance. This study was conducted with patients attending the Morrisania City Hospital Cardiac Clinic.

SUBJECTS, MATERIAL, AND METHODS

Nine patients were selected from a group of 20 who were being treated for congestive heart failure in the out-patient clinic. In all these patients symptoms and signs of failure were not controllable by means of digitalis and the usual oral diuretics (ammonium chloride, aminophylline) alone, but adequate diuresis was obtained by means of intravenous injections of mercurial diuretics.‡ These patients, all ambulatory, had been carried adequately, i.e., nocturnal dyspnea, edema, and weight had been controlled, with one or two weekly injections intravenously of 2 c.c. of a mercurial diuretic, for periods varying from a few months to three years. Of this group of patients, 9 were selected for treatment with the oral preparation of salyrgan-theophylline.† The other 11 patients could not be taken off intravenous mercurial therapy, since the severity of their symptoms did not permit any change of regimen.

Of the 9 patients studied, 6 were men and 3 were women. The age range was from 41 to 69 years: 4 patients suffered from both arteriosclerotic and hypertensive heart disease, 2 from arteriosclerotic heart disease, one from hypertensive heart disease, and 2 from rheumatic heart disease. The urines of all 9 patients, on repeated examinations, showed normal variability in specific gravity, and yielded no pathologic microscopic findings. Blood chemistry determinations were all normal.

For two weeks prior to the change from intravenous to oral mercurial therapy, the 9 patients reported to us, on printed instruction sheets, their urine outputs for the twenty-four-hour period immediately following the mercurial

*From the Cardiac Clinic of the Morrisania City Hospital, Bronx, N. Y.
Received for publication, May 21, 1942.

†Supplied by Department of Medical Research of the Winthrop Chemical Co., labelled S.T.O. 3813. Each tablet contains 80 mg. of salyrgan (30 mg. of mercury and 40 mg. of theophylline).

‡Mercupurin, salyrgan-theophylline. Each cubic centimeter contains the equivalent of 40 mg. of mercury.

injection, and for the twenty-four-hour period just preceding the next injection. This last figure represented the daily output without the influence of a mercurial diuretic, since the measurements were made several days after the effect of the drug had worn off. The patients were instructed to restrict their fluid intakes to 1,000 c.c. daily. They had been receiving 4 to 6 Gm. of ammonium chloride daily as long as they had been on intravenous mercurial therapy.

TABLE I

NAME	AGE	SEX	TYPE OF HEART DISEASE	WEIGHT BEFORE S.T.O.	WEIGHT AFTER S.T.O.	DAILY OUTPUT WITHOUT MERC. DIUR. (C.C.)	DAILY OUTPUT AFTER S.T.O. (C.C.)	DAILY OUTPUT AFTER INTRAV. MERC. (C.C.)	REMARKS
L. C.	60	M	Arteriosclerotic and hypertensive	207	207	1,000	1,500	2,500	Diarrhea
D. S.	49	F	Hypertensive	1-168	166	1,000	3,000	4,500	Onset of diuresis slow
				2-170	171	1,000	Not reported		Severe cramps and diarrhea
D. O.	50	M	Arteriosclerotic	1-175	175	800	1,250	2,000	Mild cramps and diarrhea
				2-181	181	1,000	1,100		No side effects
				3-182	178	1,000	2,000		Severe cramps and diarrhea
L. W.	55	M	Rheumatic and arterio sclerotic	1-161	162	1,000	1,250	5,000	No side effects
				2-153	146	1,000	4,000		No side effects
				3-151	147	750	2,300		No side effects
				4-		Not reported			
				5-		Not reported			
C. T.	41	F	Rheumatic	1-154	152	1,250	3,750	Not reported	Cramps and diarrhea
				2-152	151	1,250	2,750		Cramps and diarrhea
D. S.	67	F	Arteriosclerotic and hypertensive	159	157	750	1,000	2,000	No side effects, but did not feel as comfortable as after intravenous mercurial
S. K.	60	M	Arteriosclerotic and hypertensive	202	199	2,000	3,600	Not reported	No side effects
J. O.	69	M	Arteriosclerotic and hypertensive	142	142	1,500	1,250	Not reported	Cramps and diarrhea
A. N.	64	M	Arteriosclerotic	1-166	164	550	4,000	5,500	No side effects
				2-164	163	550	1,000		No side effects

Then, still keeping the patients on the same fluid intake, and maintaining the administration of ammonium chloride as before, the patients were given 5 tablets of oral salyrgan-theophylline immediately following breakfast on the

day of administration, in place of the intravenous mercurial injection. Again the patients were instructed to measure and report the urine output for the twenty-four-hour period immediately following the oral administration of this preparation, and again for the twenty-four-hour period before the next dose. During this study the patients were weighed just before the tablets were given and again forty-eight hours later.

The results of this study are shown in Table I.

ANALYSIS OF RESULTS

The 9 patients studied received oral salyrgan-theophylline a total of 18 times. The results were not reported three times, leaving a total of 15 reportable trials.

Of the 9 patients studied, one (one trial) showed a decrease in urinary output, about 15 per cent less than when not under the influence of a mercurial diuretic. One patient (two trials) showed no change in output. The other 7 patients (12 trials) all showed an increase in urinary output over that observed when not influenced by the administration of a mercurial diuretic, the increase ranging from 10 to 63 per cent; 7 trials showed an increase of 100 per cent or over; 5 trials, an increase of less than 100 per cent.

All 9 patients reported a greater increase in urinary output after receiving intravenous mercurial than was obtained by the use of oral salyrgan-theophylline. Of 8 measured results after intravenous injection, the range of increase was 66 to 900 per cent, with 7 showing an increase of 100 per cent or more and one an increase of 66 per cent.

Six of the 9 patients developed cramps or diarrhea or both after one to three doses of oral salyrgan-theophylline, which were severe enough to require that the medication be discontinued.

SUMMARY

Nine patients in congestive heart failure, attending an out-patient cardiac clinic, who were known to be well controlled by administration of intravenous mercurial diuretics, were given instead, an oral preparation of mercurial diuretic in a study to determine the usefulness of this medication in ambulatory patients. Seven of the 9 patients (77.7 per cent) showed an increase in urinary output after taking this preparation, as compared with their output when no mercurial diuretic was given. In no case was the increase in urinary output as great as that resulting when the usual dose of a standard mercurial diuretic was given intravenously. Side reactions, chiefly cramps and diarrhea, occurred in 6 of the 9 patients (66.7 per cent) and necessitated discontinuance of administration of the oral mercurial preparation.

ADENYLIC ACID AND BACTERIAL GROWTH

SAUL CASPE AND A. G. OSLER*
NEW YORK, N. Y.

DIRECT bacterial infection of the living muscle tissue is not a common phenomenon. Due to its anatomic position the only avenues for muscular infection are through the lymphatics or the blood circulation. Because the latter have their own protective mechanisms, the muscle is thus usually spared from infection. In addition to the above, we believe that the chemical changes and end products occurring during muscular metabolism are inimical to bacterial growth.

In the production of experimental streptococcic arthritis in rabbits, Hadjopoulos[1] and Burbank demonstrated that, whereas the bone marrow, muscular sheaths, and even tendons were infiltrated with streptococci, there was no evidence of the invasion of the muscle tissue. Ammonia and lactic acid are known to be inimical to bacterial growth. However, their concentration in the muscle is not sufficient to inhibit the growths of certain types of bacteria.

The work of Lutwak Mann[2] showed that washed suspensions of *Esch. coli* and of other Bacteriacea dephosphorylated and deaminated adenosine triphosphoric acid, and adenylic acid. These reactions occurred with fresh suspensions as well as with those treated with toluene, and these facts have led Lutwak Mann and others to the conclusion that these reactions are due to bacterial enzymes. What effect the adenine compounds and their dephosphorylated and deaminated derivatives have upon the growth of various types of bacteria was not determined. In order to obtain this information, we devised preliminary experiments.

Our plan, therefore, is to study the effect of adenylic acid upon the growth of various types of bacteria. The usual in vitro experiments do not correspond to the conditions that obtain in normal physiologic processes of the living organism. We desire to approximate these normal body conditions. The work of Freedman and Funk[3] offered application in this connection. These investigators were able to inhibit the growth of bacteria in beef heart broth shaken with charcoal. They postulated the theory that by this procedure a new vitamin was adsorbed upon the charcoal, a vitamin necessary for bacterial growth. By this method, we are afforded an opportunity of observing bacterial growth in a media partially depleted of a bacterial vitamin, and this experimental condition might simulate the conditions occurring in certain parts of the human body.

EXPERIMENTAL

We compare the growth of *B. coli, Staphylococcus aureus, Streptococcus hemolyticus* and *viridans* on (1) starvation media; (2) beef heart infusion; (3) beef heart infusion after treatment with charcoal; (4) beef heart infusion

*Consulting chemist and bacteriologist, New York.

Received for publication, May 1, 1942.

after treatment with charcoal and addition of 0.2 per cent adenylic acid; and (5) starvation media with addition of 0.2 per cent adenylic acid.*

The inoculum for all tests is prepared as follows: Individual organisms are grown in broth culture and are seeded onto agar slants (eighteen hours' growth). The growth is washed with saline, centrifuged, and, again washed four or five times. Then a dilute suspension of the growth is inoculated into a flask containing 10 c.c. of media. The flasks are incubated for ninety-six hours. They are then centrifuged in Hopkins tubes and read. Table I gives the results of this experiment.

TABLE I*

96 HR. GROWTH	GLUCOSE SALT SOLUTION	B.H.I. (DIFCO)	B.H.I. AFTER CHARCOAL	B.H.I. AFTER CHARCOAL PLUS ADENYLIC ACID	G.S.S. PLUS ADENYLIC ACID

				0.001+ (sediment)

The concentration of adenylic acid used in our experiments is probably comparable to the content of adenine compounds of the muscle. The work of at least two workers in this field can be used as reference for such comparison.[4, 5]

It is demonstrated that adenylic acid inhibits the growth of ordinary types of bacteria.

We are indebted to Dr. L. G. Hadjopoulos for his cooperation in these experiments.

FATAL SALMONELLA INTRACRANIAL INFECTION IN AN INFANT*

Report of a Case

W. E. Bray, M.D., and J. M. Meredith, M.D.
University, Va.

Clinically and bacteriologically the Salmonella group presents many problems.

Clinically, some species or types, as, for example, *S. paratyphi* or *B. paratyphosus A,* infect man only and cause prolonged fever and symptoms indistinguishable from typhoid fever; others, like *S. aertrycke,* cause chiefly gastrointestinal upsets, with sudden onset and short duration, called food poisoning, and are found in both animals and man; and still others, which rarely if ever infect man, like *S. pullorum,* which causes white diarrhea of chickens, are important only economically.[1]

Bacteriologically, there is not only variation in the cultural characteristics, such as in the fermentation of the various sugars, but there is marked variation in the antigen components and consequently in the serologic reactions. Following the work of White[2] (1926-1929) and of Kauffmann[2] (1929-1934) and of later workers[3] in antigen analysis, so many species or types have been described that Jordan and Burrows,[4] in their recent edition of their *Textbook of Bacteriology,* consider that simplification is essential.

The organism cultured from the case here reported was morphologically and culturally like one of the Salmonella group, especially *S. enteritidis,* and was agglutinated to a moderate titer with antisera of *S. aertrycke* and *S. schottmülleri,* but only very slightly with antiserum of *S. enteritidis.* Because of these findings and because of the unusual clinical picture, the culture was sent to the Salmonella Typing Station, located at the University of Kentucky, Lexington, Ky., for identification of the type of the Salmonella. Dr. P. R. Edwards, bacteriologist, Department of Animal Pathology, who has kindly given us permission to use his reports, found the culture to be *S. sandiego,* the antigenic formula of which is IV, V: eh enz$_{15}$.

S. sandiego was first described by Kauffmann,[5] who studied the *S. chester* group and, on the basis of the structure of the H antigen, particularly the β phase, divided the group into two serologic types: *S. chester* and *S. sandiego.*

To the *S. sandiego* type belong:

1. Two original cultures isolated by Professor K. F. Meyer of San Francisco from a case of food poisoning in an outbreak at the San Louis Rey Mission,

*From the Departments of Clinical Pathology and of Neurological Surgery, University of Virginia Hospital and School of Medicine.

Received for publication, May 27, 1942.

where two hundred persons suffered from severe abdominal pain accompanied by vomiting and diarrhea. Most patients recovered within one to two days, but some were ill for ten days or longer.

2. An old laboratory culture, No. 1254, isolated in 1929 in Denmark and mistaken for *S. reading*.

3. Culture CB 42/2, isolated from a healthy pig by Professor E. Hormaeche of Montevideo, Uruguay.

4. Culture b641, obtained from a human being by Professor Hormaeche.

5. Culture 123, obtained by Dr. P. R. Edwards, Lexington, Ky.

The antigenic formulas for these strains are given in Table I, to which we have added the formula for our strain, as determined by Dr. Edwards.

TABLE I

STRAIN	ANTIGEN FORMULA	
Original	IV, XII	eh enz$_{15}$
1254	IV, XII	eh enz$_{15}$
CB 42/2	IV, V, XII	eh enz$_{15}$
641	IV, V, XII	eh enz$_{15}$
123	IV, V, XII	eh enz$_{15}$
UVa	IV, V	eh enz$_{15}$

Dr. Edwards[6] has typed 17 cultures of *S. sandiego:* four from animals, one from sewage, and 12 from man.

The most unusual feature of the following case is the localization of the infection in the subdural space, forming an abscess. The Salmonella infections tend to localize in the bones, joints, and other tissues,[7] and certain members of the Salmonella group, notably *S. enteritidis* or Gärtner's bacillus, have frequently been reported as causing meningitis.[8]

PRELIMINARY NOTE

Baby R. M., Jr., a white male infant, aged 4½ months, University of Virginia History No. 163058, was admitted April 2, 1941, and died April 16, 1941.

The child was born at the University of Virginia Hospital on Nov. 12, 1940, and remained until Dec. 31, 1940. He was a premature child (seven months), forceps being required for delivery. His birth weight was 2,185 Gm. When discharged (Dec. 31, 1940) he was in good condition (weight 2,975 Gm.), although his head was observed to be large, even at that time. At birth the circumference of the head was 35.5 cm.; normally it is 34.7 cm.

The child was next seen on April 1, 1941 (aged 4½ months) in the pediatric out-patient department. He appeared to be very ill. His temperature was 102.2° F. (rectal). The circumference of his head was 53.2 cm. (normal, 40.5 cm.), it being tremendously enlarged. He had vomited for two days previous to his visit to the clinic.

Examination at that time (April 1, 1941) revealed what appeared to be marked hydrocephalus (Fig. 1). The fontanelles were very large and the cranial sutures were widely separated. The child gazed downward constantly in a typically hydrocephalic appearance.

REPORT OF CASE

The following day (April 2) the child was admitted to the hospital on the neurosurgical service for study and possible operation, with a temperature of 103.2° F. (rectal). Each lateral angle of the anterior fontanelle was aspirated and very sanguineous, somewhat purulent, fluid was obtained. This fluid contained 46,900 R.B.C., and 1,980 W.B.C. per cubic millimeter. The following day (April 3) the erythrocytes of the aspirated fluid were diminished in number, but the white blood cells were considerably increased (27,300 R.B.C.; 8,400 W.B.C., 84 per

cent P.M.N.); one week later (April 10) the fluid was very cloudy and contained only 680 R.B.C. but 30,150 W.B.C. per cubic millimeter. Two days before death (April 14) the fluid aspirated through the anterior fontanelle contained 42,600 W.B.C. per cubic millimeter and appeared frankly purulent, with no gross blood discernible.

Examination of the fluid aspirated through the fontanelle on two occasions, for the presence of tumor cells was negative (hematoxylin and eosin stain of centrifuged specimen).

Fig. 1.—Photograph of the patient (twenty-four hours after the first aspiration of fluid through the anterior fontanelle) taken on the day after admission to the hospital (April 3, 1941). Note the very large head, the engorged scalp veins, and the typical downward gaze of the eyeballs so often seen in hydrocephalic infants.

The blood and ventricular fluid Wassermann reactions were negative. Urinalysis revealed many large granular pseudocasts but no red blood cells and no albumin or sugar. An occasional white blood cell per high-power field was seen. Blood counts are shown in Table II.

TABLE II

DATE	HEMOGLOBIN (%)	HEMOGLOBIN (GM. %)	R.B.C. (MILLIONS)	W.B.C.
4/ 3/41 (Day after admission)	62	9.5	3.03	9,300 P.M.N. 28%, Lymph 67%, Mono. 5%
4/ 6/41	65	10.0	5.08	21,000
4/ 8/41			4.16	19,200
4/11/41			3.84	11,200
4/14/41			3.16	34,500

Bacteriologic Examination of Removed Intraventricular or Subdural Fluid.—This was done on several occasions. It soon became evident that none of the ordinary pyogenic bacteria were the cause of the infection. A Salmonella-like

organism was isolated, designated *Salmonella sandiego,* constituting the first instance of an intracranial infection from this organism in our experience.

Course in the Hospital.—The child's condition, as might be expected, was precarious at all times. He died two weeks after admission. His terminal temperature was 101° F (rectal), the temperature readings fluctuating widely, the highest reading being 105.2° F. (rectal) the day after admission. The anterior fontanelle remained very tense at all times except immediately after aspiration. Convulsions occasionally occurred. Sulfathiazole, sulfapyridine, and transfusions of blood were given. Cheyne-Stokes respiration and cyanosis were frequently observed. The immediate cause of death was respiratory failure incident to the overwhelming intracranial infection. A post-mortem examination could not be obtained.

DISCUSSION

An intracranial infection from the organism identified in this case (*S. sandiego*) is very rare. It is possible that the child had a primary (congenital) hydrocephalus on which was engrafted the Salmonella infection, since the child's head was enlarged at birth. Interest also centers on the exact location of the intracranial infection. Was it primarily intraventricular or subdural? The impression of one of us (J. M. M.) who observed the child daily in the ward was that it was primarily subdural, although this can never be proved conclusively since no burr openings were made over the cerebral hemispheres and no post-mortem examination was permitted. It is also quite conceivable that the intracranial involvement began as a purulent meningitis from a primary infection elsewhere in the body (gastrointestinal tract) or from a blood stream infection, proceeding on to gross intraventricular infection (purulent ependymitis) and subdural infection as well.

EPIDEMIOLOGY

Efforts were made to determine the manner in which the infant might have obtained such an unusual infection. Dr. T. S. Englar, Director of the Joint Health Department of the County of Albemarle (Va.) and the City of Charlottesville, kindly instituted a survey of the child's home environment in a nearby country district. His department found that the child had not been breast fed. The mother had been very careful to boil all milk before feeding the baby.

The baby's diet had consisted of boiled milk with Karo syrup added, as well as orange juice and water. He had been fed entirely by bottle and nipple, which were consistently washed and boiled. The milk was usually boiled each morning and night.

The baby's mother continually complained of feeling bad, with headache and nausea, frequently not eating at mealtimes. She did not complain of diarrhea or dysentery at any time so far as is known.

The water supply was from two open springs. Samples of water from these springs were examined in the laboratory of the Department of Preventive Medicine and Bacteriology, University of Virginia, Dr. G. M. Lawson, director. The sample from one spring showed a count of 18 colonies per cubic centimeter, with *B. coli* and *B. aerogenes* confirmed in three tubes of 10 c.c. each; from the

other spring, 38 colonies per cubic centimeter, with *B. aerogenes* confirmed in one tube of 1 c.c., and two tubes of 10 c.c.

The sewage was disposed of through a pit-type toilet located so as not to contaminate the water supply.

The home milk supply was from two cows. One had been sold before the health department survey was made; bacteriologic analysis of milk from the udders of the remaining cow (collected directly into a sterile bottle) showed a count of 56,000 with no lactose fermenters.

SUMMARY

A fatal intracranial infection due to *Salmonella sandiego,* an uncommon type of the genus, is reported in an infant.

A list of the reported cultures of this type, with their antigenic formulas, is given.

This appears to be the first report of this organism since the original description of the type.

Addenda.—Since this paper was prepared, another case of infection with *S. sandiego* in which localization of the infection occurred in the right kidney, and apparently also in the degenerated and necrotic areas of a large uterine fibroid, has been treated in the University of Virginia Hospital. The course of this illness, extending over a period of seventy-six days, was septic in character with blood stream infection, and recovery began apparently only after the infected foci were removed by surgery.

EFFECT OF INJECTION OF TISSUE EXTRACTS ON THE NUMBER OF BLOOD PLATELETS*

Alfred Uihlein, M.D., Rochester, Minn.

THIS investigation was stimulated by experiments[3, 19-21] which indicated that a thrombocytolytic agent, "thrombocytopen," can be extracted from spleens of patients who have idiopathic hemorrhagic purpura and was undertaken at the suggestion of Dr. H. Z. Giffin and Dr. J. deJ. Pemberton. Some reports in the literature demonstrated that a substance can be isolated which not only decreases the number of circulating blood platelets of animals,[2, 18, 19] but even alters the normal configuration of the megakaryocytes when cultured in vitro.[14-17] The thrombocytolytic substance apparently reduces the number of platelets, but experimentally, it does not produce purpura. During the progress of this study, several investigators[1, 4, 10, 13] reported their inability to isolate thrombocytopen, while others confirmed its presence.[5, 7, 12]

METHOD

For the purpose of investigation, extracts of 28 spleens, together with normal hepatic and lymphoid tissue from one patient, were prepared. Thirteen spleens were from patients who had idiopathic hemorrhagic purpura, five from patients who had hemolytic icterus, five from those who had Banti's disease, and one from a patient who had Hodgkin's disease. There were four normal spleens. All but three of the spleens were obtained from the operating room, and each was prepared for extraction within thirty minutes after splenectomy. Three spleens and the hepatic and lymphoid tissues were obtained within an hour and a half after death.

The tissues were extracted according to the procedure outlined by Troland and Lee.[21] Briefly, each tissue was ground in a medium-fine meat grinder and weighed. It was then placed in a jar containing acetone, the volume of which was twice the weight of the tissue. The container was sealed and permitted to remain at room temperature for about four weeks, gently agitated at least once a day. Three spleens were extracted in commercial acetone, while all other tissues were placed in reagent acetone. After extraction the mixture was filtered and centrifuged. The acetone then was removed by distillation. The residue was brown and gummy. It was mixed with a sufficient amount of distilled water to make 1 c.c. represent 1 Gm. of tissue. This aqueous mixture again was filtered and the filtrate was placed in the refrigerator where it remained for about two

Abridgment of thesis submitted to the faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of *Master of Science* in Surgery.

Work done in the Institute of Experimental Medicine, the Mayo Foundation, Rochester.

Received for publication, May 25, 1942.

weeks. If a precipitate formed, gentle agitation and passage through a Zeiss filter cleared the filtrate. A preservative was not added.*

At first, experiments were conducted on rabbits that averaged 2 kg. After a few experiments, however, rabbits were rejected because it was difficult to obtain control platelet counts from them, and rats weighing 200 Gm. (Wistar strain) were used. Control platelet counts were carried out for from one to three days prior to injection of the extract. Usually 1 c.c. of the extracted material, the equivalent of 1 Gm. of tissue, was injected intravenously; however, as much as 20 c.c. were given. Subcutaneous and intraperitoneal injections also were tried in a few instances. Following intravenous injection the number of platelets was determined at hourly intervals for the first six hours, and thereafter, every six hours until no further variation in the number of platelets was noted. Each animal received only one injection.

The method used for counting the platelets differed slightly from that of Troland and Lee.[21] A 2 per cent solution of sodium citrate in normal saline solution, as described by Ottenberg and Rosenthal but modified by the Division of Clinical Pathology of the Mayo Clinic, was used instead of the Rees-Ecker solution, as the latter diluent contained too many platelet-like artifacts. The solution of sodium citrate contained 2.26 Gm. of sodium citrate, 1.8 Gm. of sodium chloride, and 220 c.c. of distilled water. The solution was thrice filtered into a sterile flask. The diluent was always freshly prepared and was used at room temperature.

Blood was obtained by cutaneous puncture of the ear of the animal. The first few drops were discarded,[8, 9] and specimens were not collected unless the blood flowed freely without compression of the ear. However, gentle compression of the ear was at times necessary after injection of the extract because the blood flow was decreased; the cause of this was not apparent. The blood was drawn up to the 0.5 mark in an erythrocyte pipette and diluted to 1.1 with the solution of sodium citrate. This mixture was agitated gently by hand for three minutes. Following a five-minute quiescent period a third of the contents in the bulb of the pipette was expelled, and succeeding drops were carefully placed under each half of the cover slip on a modified Neubauer counting chamber. The chamber was then placed on a moistened piece of filter paper in a Petri dish for ten minutes to avoid desiccation and to permit settling of the cells. The number of platelets and erythrocytes in eighty small squares was counted with a high power objective and a 10× ocular. Computation was made in the usual manner. Only a variation of ±200,000 in each count was considered significant.

RESULTS

Extracts of 28 human spleens, and one extract of hepatic and one of lymphoid tissue were prepared. Of these, four spleens, the liver and lymph nodes were obtained as controls. Various responses were obtained. The first two spleens extracted were from patients who had idiopathic hemorrhagic purpura; these spleens were only slightly larger than normal (Table I). The extracts of these two spleens, when injected, produced a dramatic fall of number of thrombocytes of the first rat from a preinjection level of 700,000 in each cubic

*I wish to express my appreciation to Dr. A. E. Osterberg for his assistance in preparation of the tissue extracts.

millimeter of blood to 40,000 in twenty-four hours (Fig. 1). Blood smears, stained with Wright's stain, confirmed the presence of thrombopenia. The thrombopenia was prolonged for seventy-two hours, after which the number of platelets gradually returned to the preinjection level. Moreover, injection of these extracts was followed by a similar response in eleven other normal rats, each of which weighed 200 Gm. All the animals appeared ill at the height of the thrombopenia. At the end of approximately a week these extracts became extremely toxic. Subsequently all animals died within six hours after the injection.[11] Hemorrhage or purpuric spots did not appear, nor could any definite change be noted in the bleeding or coagulation time. The number of erythrocytes did not vary significantly.

TABLE I

CASES IN WHICH THE SPLEEN WAS EXTRACTED

CASE	SEX	CONDITION	WEIGHT OF TISSUE EXTRACTED (GM.)
1	F	Hemorrhagic purpura, idiopathic	115
2	M	Hemorrhagic purpura, idiopathic	110
3	F	Hemorrhagic purpura, idiopathic	80
4	F	Hemorrhagic purpura, idiopathic	90

20	M	Banti's splenomegaly	320
21	M	Banti's splenomegaly	300
22	M	Banti's splenomegaly	382
23	M	Banti's splenomegaly	282
24	M	Hodgkin's splenomegaly (grade 4 sarcoma type)	590
25	F	Normal spleen	36
26		Normal spleen	140
27		Normal spleen	125
28		Normal spleen	125
29		Normal liver	490
		Normal lymph nodes	25

Three other extracts of spleens obtained from patients who had hemorrhagic purpura produced only a small transitory decrease in the circulating platelets in six hours; one other extract of a spleen from a patient who had hemolytic icterus produced a definite decrease in the number of platelets, which lasted only a few hours. None of these produced the striking thrombopenia of the first two extracts (Fig. 1). These extracts, however, never became toxic, although several animals received injections. The extracts from the remaining tissue did not produce any significant decrease of the number of blood platelets or erythrocytes after injection (Fig. 1). Even injection of larger amounts of the extracts, as high as 20 c.c. failed to reduce the number of platelets. However, all animals ap-

peared apathetic for short periods after the injections, a result suggestive of an indeterminate type of reaction.

COMMENT

Although thrombocytopen could not be extracted consistently from all the spleens of patients who had hemorrhagic purpura, its presence was indicated in some of them. Five extracts of the 13 spleens from patients who had idiopathic hemorrhagic purpura produced a certain amount of thrombolytic activity. Moreover, one of five spleens from patients who had hemolytic icterus apparently contained a thrombocytolytic substance (Table II). The fact that all animals

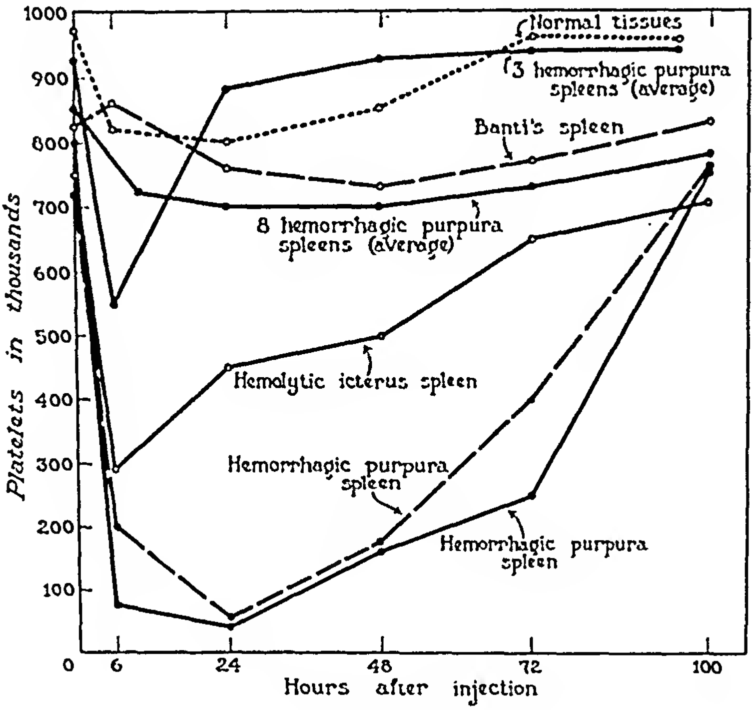

Fig. 1.—Effect of injections of various tissue extracts on the circulating blood platelets of the albino rat.

were apathetic after the injection of the extracts suggests an anaphylactoid response, probably nonprotein in nature since the acetone is believed to remove all the protein. The extracts were impure and the lipoid fraction may have contained substances which produced this effect.

Neither extraction with reagent acetone or with commercial acetone nor distillation of the acetone fraction by various methods seemed to influence the thrombolytic activity of the extracts.

No explanation can be given for the toxic manifestations encountered with the first two extracts used. Dilution of the material and filtration through a Zeiss filter failed to diminish the toxicity. It is not likely that failure of the number of blood platelets to decrease could be attributed to the citrate solution. Platelets counted after dilution with a 2 per cent solution of sodium citrate remained consistently constant prior to injection, and this result suggested that the method was satisfactory. With the Rees-Ecker stain a platelet count that is too high rather than too low is likely to be obtained.

Rats were used instead of rabbits principally because the control platelet counts were more constant and because these animals were more available. Since most of the data in the literature on this problem were derived from experiments on rabbits, some investigators may criticize these results as incomparable with the results of earlier studies. It is doubtful, however, whether the type of laboratory animal used is a factor in influencing the results, since rabbits also were given injections of the extracts in the first few experiments. With rabbits the response of the platelets was not unlike that found among rats.

TABLE II

RESPONSE OF PLATELETS TO INJECTION OF TISSUE EXTRACT

CASES IN WHICH SPLEEN WAS EXTRACTED		DECREASE IN NUMBER OF PLATELETS	
CONDITION	NUMBER	100,000 AND MORE	LESS THAN 100,000
Idiopathic hemorrhagic purpura	13	5	8
Hemolytic icterus	5	1	4
Banti's disease	5		5
Normal spleen	4		4
Normal liver	1		1

SUMMARY

The results of this study neither clearly demonstrate nor definitely deny the existence of a thrombocytolytic substance, "thrombocytopen," in extracts of spleens from patients who had idiopathic hemorrhagic purpura. Because of the inconsistency of the results, the study indicates that a better method of extraction is essential. Twenty-eight spleens, liver tissue, and lymphoid tissue were obtained from patients and the thrombocytolytic substance was extracted.

Thirteen spleens from patients who had hemorrhagic purpura were extracted. Extracts from two produced a considerable drop in the circulating blood platelets; in three they produced a moderate decrease, while the rest gave no response. Five spleens from patients who had hemolytic icterus were extracted; the extract of one spleen apparently lowered the number of platelets. This response was repeated in other animals and was not eliminated by heating the extract.

The decrease of the number of platelets and the lethargic state of the animals after injection suggested the presence of anaphylaxis or a histamine-like reaction, since the symptoms appeared shortly after administration of the extract and disappeared within a few hours.

A PRELIMINARY REPORT ON THE TREATMENT OF BACILLARY DYSENTERY WITH SUCCINYL SULFATHIAZOLE*

EDGAR J. POTH, PH.D., M.D., BEACH M. CHENOWETH, JR., M.D., AND F. LOUIS KNOTTS, M.D., BALTIMORE, MD.

THE introduction of sulfonamide therapy has been the most significant recent advance in the treatment of bacillary dysentery. The dysentery organisms are particularly susceptible to the antibacterial action of several members of this series of drugs. Sulfapyridine[1, 2] and sulfathiazole[3-7] are probably the most effective sulfonamides reported so far. They would be entirely satisfactory if they were less toxic.

Cooper and Keller[8] showed that a single dose of 2 mg. of sulfathiazole given orally at the time of intraperitoneal injection of a suspension of 1,000 minimal lethal doses of *Shigella paradysenteria* Flexner protected mice against the infection. Under similar conditions sulfanilamide was ineffectual.

*From the Department of Surgery and the Department of Pediatrics, the Johns Hopkins University School of Medicine, Baltimore.
This work was supported by a grant from Sharp & Dohme, Philadelphia, Pa.
Received for publication, June 6, 1942.

The successful use of various sulfonamides would indicate that many of these compounds are effective against bacillary dysentery when they are absorbed slowly enough from the gastrointestinal tract to allow the concentration of the drug to reach bacteriostatic levels in the bowel. An important property of an active compound ideally suited to the treatment of bacillary dysentery requires, therefore, that the drug be sparingly absorbed from the bowel. This property will keep the drug where it can be directly active against the bacteria and will minimize general toxicity.

TOXICITY OF SULFAPYRIDINE, SULFATHIAZOLE, AND SULFANILYLGUANIDINE

A review of the literature on the use of sulfapyridine, sulfathiazole, and sulfanilylguanidine shows that these compounds cause toxic reactions when used to treat bacillary dysentery.

Sulfapyridine is the most toxic. Ravenel and Smith[2] state, "In a few patients sulfapyridine produced marked restlessness; this was controlled with phenobarbital."

Welch[9] found more severe manifestatiosn of toxicity: "Sulfapyridine administration is followed by symptoms of nausea and vomiting which occur to varying degrees in 30 to 40 per cent of children under treatment. Too frequently the vomiting makes the therapy disagreeable and too often is so severe that it necessitates discontinuing the drug."

The toxic manifestations due to sulfathiazole are less severe. One patient we treated developed a rash which necessitated discontinuance of sulfathiazole. A more serious sequence was reported by Taylor.[4] An infant, 4 months of age, received 0.9 Gm. of sulfathiazole in the presence of a slight jaundice. The jaundice increased and the drug was discontinued. The child died twenty-three days later of the bacillary dysentery. Although the jaundice might have been due to multiple transfusions of blood, it was for fear of a drug reaction that sulfathiazole was withheld.

Of the three drugs used most widely in the treatment of bacillary dysentery, sulfanilylguanidine appears least toxic. Lyon[10] observed mild toxic manifestations, consisting of (1) disturbances of sensorium, (2) conjunctivitis, and (3) "discoloration" of the skin. These evidences of mild toxicity occurred in four of the 23 cases treated.

SUCCINYL SULFATHIAZOLE AS A CHEMOTHERAPEUTIC AGENT LOCALLY ACTIVE IN THE BOWEL

The experimental and clinical foundation for the use of succinyl sulfathiazole in the treatment of bacillary dysentery was laid by Poth, Knotts, Lee, and Inui[11-13] These authors demonstrated that this compound has much greater local activity against the coliform organisms in the bowel than sufathiazole and sulfanilylguanidine. The physical character of feces is profoundly altered by the action of succinyl sulfathiazole. The feces become practically odorless.

Furthermore, it has been shown that the toxicity of this drug is unusually low. Approximately 5 per cent of the ingested compound is excreted by the kidneys when diarrhea is absent. In the presence of diarrhea an even smaller proportion of the therapeutic dose is recovered from the urine.

(c)—0.75 Gm. as an initial dose.

TREATMENT OF BACILLARY DYSENTERY WITH SUCCINYL SULFATHIAZLE*

The usual general symptomatic treatment was given all patients. This regimen included the administration of adequate parenteral fluids and electrolytes to combat dehydration when the need for this was indicated. No patients received transfusions of whole blood or plasma for the treatment of the dysentery. One patient did receive a single transfusion of whole blood because of a long-standing nutritional anemia. The diagnosis of bacillary dysentery was confirmed bacteriologically in all cases included in this study.

The drug was given by mouth, and the dosage varied from 0.25 Gm. to 1.0 Gm. per kilogram daily, divided into six equal portions. The length of treatment varied from two to seventeen days. As indicated in Tables I and II, there were no failures and no deaths. The patients ranged in age from 8 weeks to 83 years.

*This patient was in extremely poor condition, with malnutrition and decubitus ulcers, and showed a rash following sulfathiazole therapy without benefit to dysentery before succinyl sulfathiazole treatment was instituted. Treatment was continued much longer than necessary.

(a)—0.25 Gm. per kilogram as a single initial dose.

b —0.5 Gm. per kilogram daily for two days, then 0.25 Gm. per kilogram daily. Daily dosage is divided into six equal portions and given at four-hour intervals.

The data recorded in Table I indicate that the response of children and infants suffering from bacillary dysentery when treated with succinyl sulfathiazole is prompt whether treatment is begun early or late in the disease. The response is equally good with the smaller doses as with the larger. The temperature returned to normal in twenty-four hours or less in all instances except one. In this case the temperature became normal in thirty-six hours. The results of treating ten adults with bacillary dysentery with succinyl sulfathiazole are summarized in Table II. The response to therapy is again prompt regardless of the duration of the disease.

The number of patients in this series was insufficient to determine accurately the minimum dosage of drug and the shortest period of therapy required for the successful treatment of bacillary dysentery with succinyl sulfathiazole. It is obvious, however, that in most instances unnecessarily large quantities of drug were given for longer periods than required. In fact, the response was better in those patients receiving the smaller doses. Bacteriologic studies showed the *Shigella paradysenteriae* organisms to be especially susceptible to the anti-

*The succinyl sulfathiazole (sulfasuxidine) used in this study was supplied by Sharp & Dohme, Philadelphia, Pa.

bacterial action of succinyl sulfathiazole. The dysentery organisms ordinarily disappeared from stools within forty-eight hours, whereas significant lowering of the coliform bacteria required two or three days of additional therapy.

It is especially significant that the response to succinyl sulfathiazole is immediate, although the disease has been present for as long as three months before treatment is undertaken. This result is in contradistinction to the observations made by Lyon and Marshall regarding the efficacy of sulfanilylguanidine. As stated by Lyon:[14] "The drug appears to be most efficacious when administered during the first 3 to 4 days after onset of fever or diarrhea. Although the percentage of failures may be higher when the drug is not given until after the fifth day of illness, it has been observed to be effective at times even when given later in the disease."

Marshall, Bratton, Edwards, and Walker[15] say: "Ten children were treated late in the disease, the institution of chemotherapy varying from the 4th to the 14th day of the disease. In this group the results were not uniform. Some cases showed the same striking improvement that occurred in the children treated early, but the majority ran a course uninfluenced by the administration of sulfanilylguanidine."

It appears that sulfanilylguanidine is most effective against bacillary dysentery if the treatment is started early. It may fail to influence the course of the disease if treatment is delayed.

DISCUSSION

While the results of treating bacillary dysentery with the sulfonamides are so good in the United States, it must be realized that this outcome is partly due to the excellent state of nutrition usually encountered here. In areas where states of poor nutrition exist, especially among children, mere bacteriostasis does not give such brilliant results, because the diarrheas of the specific bacillary dysenteries are complicated by malnutrition. Under these circumstances attention to general care, fluid, and electrolyte replacement, and nutrition must be held of equal importance with specific drug therapy.

Under ordinary conditions of our national civilization, sanitary safeguards and food protection are developed to a high degree and bacillary dysentery among adults is not a serious problem. In the armed forces, however, men in strange climates and frequently in unsanitary surroundings are unduly exposed, and infection of the adult becomes a problem of major importance. Because of the apparent great efficacy of succinyl sulfathiazole in bacillary dysentery and the absence of toxic symptoms due to the administration of this drug, it would be highly desirable to consider the use of succinyl sulfathiazole as a prophylactic agent. A small quantity of drug given in the daily ration of men in areas of heavy exposure might offer protection. Such a protective dose might be surprisingly small; and in the absence of any effect on the sensorium, as determined by reaction time, and so on, the drug could be administered to great advantage.

The doses given in the cases of bacillary dysentery reported here may well be much larger than is required. No toxicity to the drug has been observed in any of these patients, and there were no instances where the drug failed to ar-

rest the disease in a very short time. Since the minimum effective therapeutic dose of succinyl sulfathiazole has obviously not been established, a satisfactory prophylactic dose might be surprisingly small.

Because sulfathiazole is highly effective in bacillary dysentery, because the activity of succinyl sulfathiazole is probably due to the degradation product, nascent sulfathiazole, and because succinyl sulfathiazole can be maintained in high concentration in the bowel with only slight absorption and without the development of toxic manifestations, it is not surprising that succinyl sulfathiazole in tolerated therapeutic doses should have a pronounced antibacterial activity against the organisms of bacillary dysentery. In all fairness it should be stated that during the past summer bacillary dysentery was not prevalent, and the disease might have been relatively mild. This communication should, therefore, be regarded as a preliminary report. Kirby and Rantz[16] have, however, succeeded in curing bacillary dysentery carriers with succinyl sulfathiazole.

SUMMARY

The treatment of bacillary dysentery with a new chemotherapeutic agent, succinyl sulfathiazole, is presented. The drug is equally effective in both the acute and the more chronic forms of the disease. All cases of bacillary dysentery treated responded promptly. The administration of the drug caused no untoward toxic manifestations.

We wish to thank Dr. Samuel Revell, of the University of Maryland School of Medicine, and Lt. David W. Exley, of Camp Jackson, South Carolina, for the privilege of including in this report cases of bacillary dysentery treated under their direction.

A NEW HYPOTHESIS OF THE PRODUCTION OF THE T WAVE IN THE ELECTROCARDIOGRAM BASED ON ELECTROKINETIC PHENOMENA*

J. Roscoe Miller, M.S., M.D., F.A.C.P., and Roy F. Dent, B.S., M.D.
Chicago, Ill.

THE purpose of this paper is to describe a possible mechanism for the production of the T-wave component of the electrocardiogram and the experimental procedure followed in its preliminary study. This study was begun with the hope that a more logical and concrete explanation of the electrobiologic phenomena responsible for this phase of the cardiogram could be found than those explanations now current.

In general, it is accepted that the T wave represents the disappearance of the electric disturbance responsible for the QRS deflection, which phenomenon has been variously termed repolarization, return to the resting state, end deflection of the QRS, etc. The exact manner in which this occurs, however, is disputed. The earlier hypothesis states that the character of the T wave is determined by the vectorial summation of the last portions of two out-of-phase monophasic waves.[1-5] More recently, with the better understanding of the nature of the QRS complex and its relation to myocardial excitation, there has developed the concept that the T wave represents a simple retreat of the wave of excitation, i.e., doublets of retreat.[6]

Without entering into a detailed examination of the two exact mechanisms, either explanation, if correct, should answer questions directed at the broader concept that the T wave is a disappearance phenomenon of an electric disturbance which in its invasion of the myocardium inscribes the QRS complex. One question which immediately rises is why the disappearance of the wave of excitation normally should involve a larger quantity of electricity than that involved in its entrance or invasion. This disparity can be demonstrated readily by comparing the sum of the areas under the QRS and T waves in the normal electrocardiogram taken from enough points over the body surface to encompass the heart completely.[6]† Other questions dealing with specific changes in the QRS without corresponding changes in the T wave, and vice versa, may be asked, and many will be unanswered. For instance, it is a common observation that the T waves increase in magnitude in hyperthyroidism without a corresponding increase in the QRS. If they were an expression of different phases of the same phenomenon, this hardly would seem likely.

*From the Department of Medicine, Northwestern University Medical School, Chicago.
Received for publication, June 15, 1942.

†The electrocardiograph machine is essentially a recording voltmeter which draws the minimum current from the electrical source. Thus the electrocardiogram is a potential-time tracing and the areas under the tracing are a measure of the quantities of electricity involved in each portion of the electrical cardiac cycle.

Another reason for this investigation deals not with the inadequacies of the current explanations but with the inherent electrodynamic characteristics of the T wave itself. A close study of the normal ventricular QRS-T complex shows that the QRS component and the T component are entirely different in form, duration of existence, and rate of change. The QRS tracing has a steep front and an equally steep decline, while the T-wave has a smoothly changing front, a more gradual rate of change, and persists for a much longer time. If the T-wave potential were dependent on cardiac muscular contraction, it would seem that the shape of the tracing could be correlated with a possible mechanism of development; that is to say, the shape would more nearly reflect its manner of production. Further, the greater quantity of electricity involved in the T wave could be explained, for in contracting the heart does work and is, therefore, potentially capable of producing electricity. Obviously, this idea would be untenable at once, were the T wave to be inscribed at any period in the cardiac cycle other than that of cardiac systole, or even begin before or persist after systole. This, however, is not the case, as can be shown by simultaneous intraventricular pressure and electrocardiographic recordings.

The association of the T-wave potential with myocardial activity is not new. Several interesting references to this possibility have appeared in the literature.[7, 8] One reference is to the specific idea to be outlined in the following paragraphs.[9]

In considering the conditions obtaining in the myocardium during systole which could convert mechanical energy into electrical, it is reasonable that those which are involved in a displacement phenomenon are the most likely subjects of investigation. On this hypothesis, then, the intramural displacement of fluids, both intercellular and capillary, suggests itself as a possible source by reason of the electrokinetic phenomen of streaming potentials.[10] The question is, will there by a sufficient pressure gradient along the intramural paths open to the blood, tissue fluid, and lymph to produce an appreciable electrokinetic effect?

From the equation for streaming potentials,

$$H = 8.48 \times 10^{-8} \frac{\zeta D P}{n K_S}$$

where H = Stream potential in millivolts
ζ = Potential of the double layer
n = Coefficient of viscosity
D = Dielectric constant
P = Pressure in cm. Hg
K_S = Specific conductivity in mhos

it is seen that for a given capillary system, the potential is directly *proportional* to the pressure, the dielectric constant, and the zeta potential; and inversely proportional to the viscosity and the *conductivity*. *A simple substitution* of the constants for whole blood at body temperature and an assumed value of 50 millivolts for the potential of the double layer will show, *however*, that the pressure will have to be high if the potential is to be of the *order of magnitude* necessary to produce the T wave. Calculations will readily show that ventricular

intramural stress can attain values of 40 cm. Hg throughout most of the wall and values of 60 cm. Hg at the base where the muscle fibers taper down to insert in the valve rings and intervalvular fibrosa.

As a preliminary test of the foregoing reasoning, dead hearts were perfused through the left coronary artery with various fluids (5 per cent glucose, 0.2 to 0.9 per cent sodium chloride, whole heparinized blood), and the potential across the anterior wall of the left ventricle was measured at various intramural pressures. At pressures between 20 and 40 cm. Hg significant potentials were developed, and the variations were in agreement with those predicted from the equation, namely, that the low conducting solutions produced the largest potential and the more conducting solutions the smaller potential, and that the potential was directly related to pressure. The potential developed with blood, which is the one of interest, was 0.5 millivolts at 40 cm. pressure. It should be noted here that the potentials developed varied considerably with the individual hearts and appeared to depend on the time dead, since higher values were obtained with the fresher material. These experiments, therefore, are not quantitative but qualitative, and the results are of value only in that they demonstrate that the internal architecture of the ventricular wall affords a capillary system which, when there is streamed through it a fluid with the comparatively high electrolyte concentration of whole blood, is capable of producing significant streaming potentials.

The question of the exact manner in which the blood and extracellular fluid may be displaced or squeezed about during ventricular systole to produce streaming potentials, cannot be answered dogmatically. The most logical sequence would seem to be a progressive "wringing out" of the myocardium as contraction progresses to a maximum. That blood, at least, is "wrung" out during systole is shown by the coronary (venous) outflow which occurs at this time in the cardiac cycle.[11, 12] For any given segment of myocardium, the sign of the developed potential would be negative to positive when progressing in the direction of the intermuscular fluid displacement.

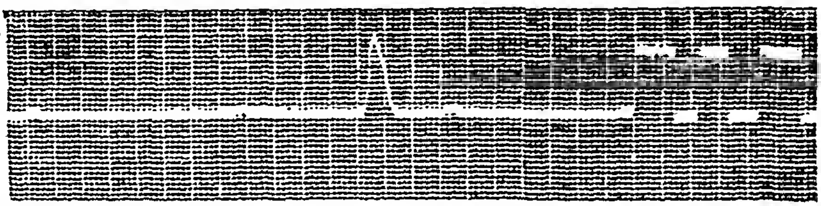
From the foregoing it can be postulated that regardless of the manner in which an intramyocardial pressure gradient is produced, whether by the actively contracting heart or by a force applied externally, just so long as it exists flow potentials should be developed. Thus, external energy applied to a heart rendered unresponsive to electrical and mechanical stimuli should produce a potential the characteristics of which are similar to those of the normal T wave as regards magnitude and rate of change. With this idea in mind, then, the following experiments were performed.

Series I.—Method. Dogs anesthetized with nembutal were given 40 c.c. of a 20 per cent solution of magnesium sulfate intravenously in order to decrease the irritability of the myocardium.[13] The thoracic cavity was then opened, care being taken to keep the field dry. The animal was connected through electrodes to the right foreleg and left hind leg to a string galvanometer electrocardiograph. The heart was then stimulated by means of a probe, and records were made of the resulting ectopic impulses. When stimulation ceased to produce an impulse, the heart was grasped in the hand which had been insulated by means of a rubber glove, and roughly bumped about the chest cavity to determine the amount of potential, if any, developed by such a procedure. With the electrocardiograph

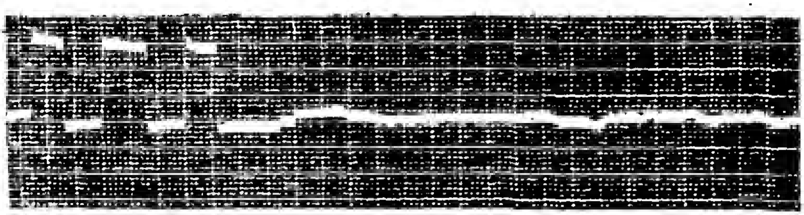
recording the heart was then forcibly constricted and suddenly released, or pressure was maintained for a period of several seconds.

Results. Cardiac stimulation produced ectopic impulses for a period varying up to twenty minutes after the chest cavity was opened. As will be seen from Fig. 1*A* a period was finally reached when stimulation produced an impulse without demonstrable contraction or T wave. Fig. 1*B* shows the result of movement of the heart and mediastinal structures. As will be seen, no significant potential was developed despite the fact that the contents of the chest were moved about vigorously, and the string was loosened to exaggerate the effect of any movement. Fig. 1*C* shows the result of constriction of the heart before irritability had entirely disappeared. Here it will be seen that there was a sudden production of a potential which gradually returned toward zero.

A.



B.



C.

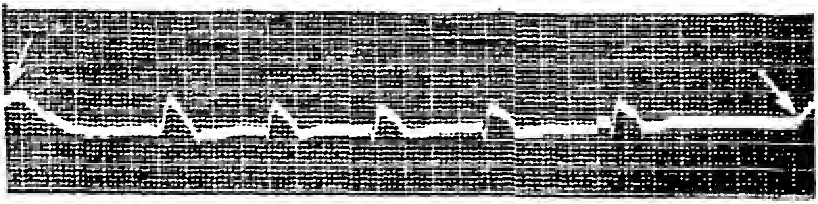


Fig. 1.—*A*, Stimulation of myocardium producing an impulse without demonstrable contraction or T wave. *B*, Vigorous movement of the heart and mediastinal structures. *C*, Arrows indicate application and relaxation of pressure. Note ectopic impulses occurring during this period.

At the same time several ectopic impulses arose from the yet irritable muscle, thus demonstrating that the potential that developed by squeezing the heart was independent of spontaneous impulses. Fig. 2*A* shows the result of sudden constriction of the heart with immediate relaxation, while Fig. 2*B* shows constriction with maintenance of pressure and the return of the potential to zero upon relaxation.

After irritability had ceased there was a period of from five to twelve minutes when the above results could be obtained at will. At the end of that time changes had occurred in the tissue which resulted in adventitious voltages due to development of local concentration cells, so that any movement of the thoracic structures would produce unlimited bizarre potentials.

Series II.—Method. These experiments were conducted to confirm previous observations regarding the time relationship of changes in intraventricular pressure to the T wave in the electrocardiogram. This was done by simultaneously recording on the electrocardiogram the pressure in the left ventricle and carotid artery.[14]

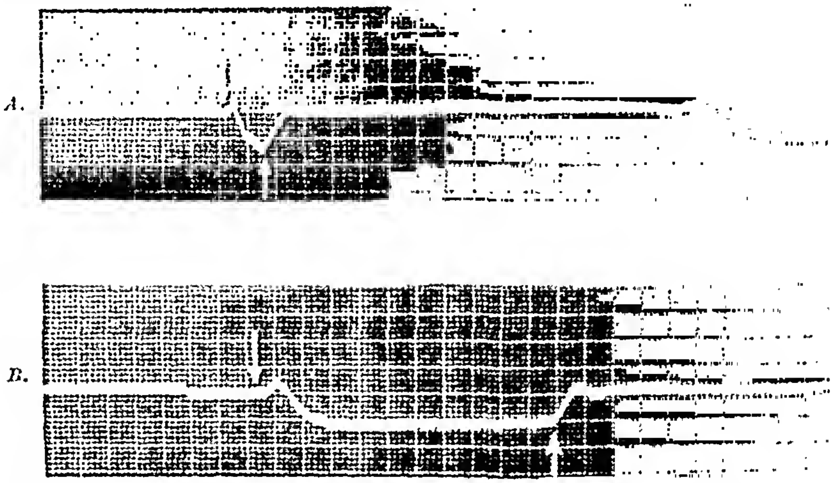

Fig. 2.—*A*, Constriction of heart with immediate relaxation. *B*, Constriction with maintenance of pressure and sudden relaxation.

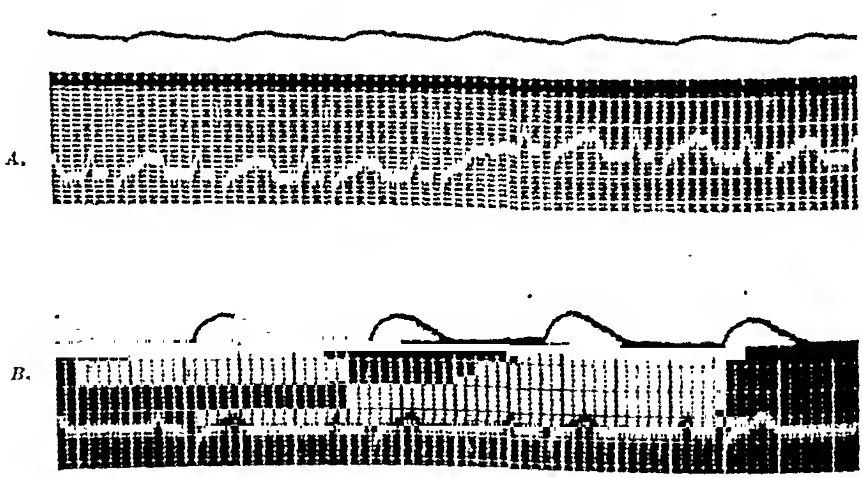

Fig. 3.—*A*, Simultaneous recording of carotid pressure and electrocardiogram. *B*, Left intraventricular pressure and electrocardiogram.

Results. Fig. 3*A* shows the correlation of increases in carotid pressure with the T wave and Fig. 3*B* shows changes in the left intraventricular pressure and the relationship of these changes to the T wave. It will be seen that in each case rise of pressure occurs at the same time as the T wave and that the latter is always confined within the time limits of the former.

SUMMARY AND CONCLUSIONS

The nature of the T wave in the electrocardiogram suggests that it is due to an electrokinetic cause and does not represent retreat electric disturbances.

The structure of the heart with its capillary bed is such that contraction could produce streaming potentials of the order of magnitude of the T wave. Pressure perfusion of the heart showed this to be entirely possible. Constriction of the unresponsive heart likewise produced this phenomenon. In addition it is shown that the T wave corresponds in time to the increase in pressure in the left ventricle. These observations suggest that contraction of the heart with its resultant streaming potentials is responsible for the T wave in the electrocardiogram.

Series II.—Method. These experiments were conducted to confirm previous observations regarding the time relationship of changes in intraventricular pressure to the T wave in the electrocardiogram. This was done by simultaneously recording on the electrocardiogram the pressure in the left ventricle and carotid artery.[11]

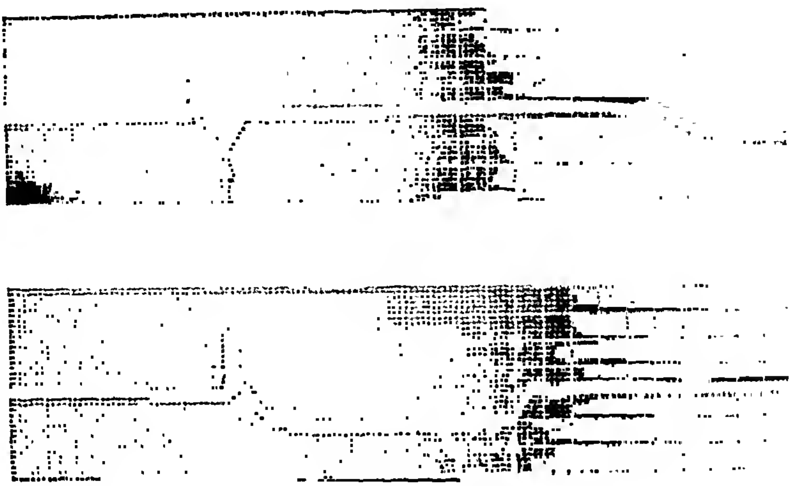

Fig. 2.—*A*, Constriction of heart with immediate relaxation. *B*, Constriction with maintenance of pressure and sudden relaxation.

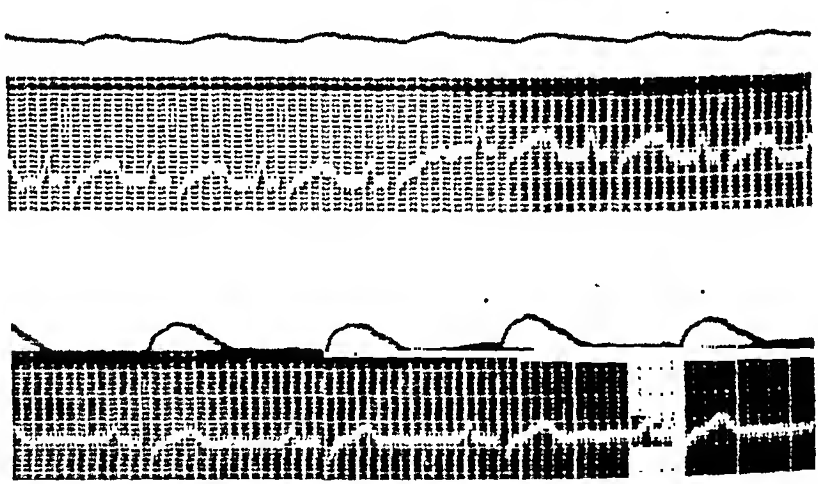

Fig. 3.—*A*, Simultaneous recording of carotid pressure and electrocardiogram. *B*, Left intraventricular pressure and electrocardiogram.

Results. Fig. 3*A* shows the correlation of increases in carotid pressure with the T wave and Fig. 3*B* shows changes in the left intraventricular pressure and the relationship of these changes to the T wave. It will be seen that in each case rise of pressure occurs at the same time as the T wave and that the latter is always confined within the time limits of the former.

SUMMARY AND CONCLUSIONS

The nature of the T wave in the electrocardiogram suggests that it is due to an electrokinetic cause and does not represent retreat electric disturbances.

The structure of the heart with its capillary bed is such that contraction could produce streaming potentials of the order of magnitude of the T wave. Pressure perfusion of the heart showed this to be entirely possible. Constriction of the unresponsive heart likewise produced this phenomenon. In addition it is shown that the T wave corresponds in time to the increase in pressure in the left ventricle. These observations suggest that contraction of the heart with its resultant streaming potentials is responsible for the T wave in the electrocardiogram.

CLINICAL CHEMISTRY

THE SIGNIFICANCE OF THE URINARY AMMONIA*

A. P. BRIGGS, AUGUSTA, GA.

CONSIDERABLE evidence has accumulated which indicates that it may be necessary to abandon one of our most time-honored concepts: the belief that secretion of ammonia by the kidneys serves in some way to maintain the acid-base balance of body fluids. Indeed, there is reason for suspecting that it has been carried along for a good many years by a combination of inertia and complacency.

The first note of dissension came in 1932 when it was observed that the acidosis of nephritis was not necessarily of the base deficit type, although the capacity for production of ammonia in this state was definitely subnormal. It was pointed out then that all observed facts relating to the secretion of ammonia were consistent with the hypothesis that ammonia production simply operates as a local protective mechanism to prevent excessive tubular acidity

Subsequently a number of special instances were observed in which the activity in production of ammonia was not that to be expected from the conventional theory but more in accord the dissenters' viewpoint.

This evidence will be reviewed briefly in the following sections and certain evidence provided by recent developments in the field of renal physiology will be presented.

CRUCIAL EXPERIMENTS

It should be obvious that the classical concept is based on circumstantial evidence which is perfectly compatible with either view, and that the whole question appears, superficially, to be merely a matter of words. Increased production of ammonia was observed to accompany increased excretion of acid, administered or metabolic. The ammonia was previously thought to be formed from neutral urea by the liver and perhaps by other tissues; secretion of a part of such acid in the form of ammonium salt was assumed to spare fixed alkali of the blood plasma. This assumption was entirely justified up to the time of the publication of the work of Nash and Benedict,[1] which indicated the kidney to be the organ of ammonia production. But the assumption, which has generally been made since then, that substitution of ammonia is part of the mechanism through which fixed base is reabsorbed from the glomerular fluid, and that it responds to requirements of the body for conservation of fixed base, is entirely gratui-

Received for publication, August 12, 1942.

tous—it is just as easy to suppose that production of ammonia by the tubules *follows* the reabsorption of fixed base as a result of irritation from rejected acid in the tubular fluid.

Since the acid-base balance of the blood and urine each deviates from the normal in the same direction, in most clinical and experimental states, it is impossible to tell from studies of such states whether fluctuations of ammonia are following changes in the plasma or renal tubules. There are available, however, a few studies in which the acid-base balance of the urine fluctuates in a direction opposite to that of the plasma. Such studies give crucial evidence.

EXPERIMENTS WITH SODIUM SALTS OF LOW THRESHOLD ACIDS

Hendrix and Sanders,[2] extending an experiment of Cushny,[3] observed that an acid urine may be formed following the administration of dibasic sodium phosphate or sodium hippurate, because the low threshold acids are not so actively reabsorbed by the renal tubules as is sodium. They also observed that production of ammonia was increased under these conditions in spite of the fact that the blood was "undoubtedly more alkaline." In my own studies with the sodium salt of another low threshold acid, sulfuric, similar changes were observed; the results were clear-cut following subcutaneous injection in the dog.[4]

The fluctuations of ammonia in these experiments, it should be observed, were parallel to the acid-base changes in the urine and were opposite to those of the plasma. They show clearly that production of urinary ammonia is not determined by the needs of the body for conservation of fixed base, for in each case the body was burdened with an excess of sodium. They strongly suggest that it is the acidity of the fluid flowing through the tubules which determines the level of ammonia production.

EXPERIMENTS WITH POTASSIUM CHLORIDE

Potassium chloride is a neutral salt which makes the urine alkaline for the reason that potassium, a low threshold base, is excreted much more rapidly than chloride. Consequently, the residual chloride which is left within the body causes an acid-base shift in the direction of acidity, similar to that which follows the administration of calcium chloride or hydrochloric acid.

Experiments with potassium chloride, administered orally or subcutaneously, have shown ammonia production to be immediately suppressed.[4] They make it clear that an excess of acid within the body is not an adequate stimulus for ammonia production. Again there is the suggestion that the acidity of the fluid flowing through the tubules is the determining factor.

THE INFLUENCE OF DIURESIS ON WASTE OF FIXED BASE AND ON AMMONIA PRODUCTION

The diuresis caused by drinking distilled water or by intravenous infusion of solutions of neutral substances, such as urea, results in the urinary waste of sodium bicarbonate. Presumably the rapid rate of flow through the tubules handicaps the mechanism of reabsorption of this vital plasma alkali. In the diuresis studies of Hendrix and Calvin[5] the plasma bicarbonate was lowered by as much as 15 per cent. But the ammonia mechanism fails to respond to the

base-deficit type of acidosis so produced,[6, 7] as it certainly should if it followed needs of the body for conservation of fixed base. This failure is in perfect harmony with the view which relates stimulation of ammonia production to increased tubular acidity. Such a diuresis does not produce an acid urine.

THE CONSERVATION OF FIXED BASE IN NEPHRITIS

There has been some confusion and controversy concerning the influence of nephritis on the renal mechanism for conserving fixed base. It is true that the capacity for production of ammonia is impaired with the destruction of many nephrons, and in such cases there is, occasionally, some evidence of base waste or depletion. The confusion is chiefly due to the obligation usually felt for incriminating the deficient ammonia mechanism as a causative factor—almost always it is possible to point to some other factor which might just as well be responsible.

Low levels of plasma fixed base are frequently encountered with the onset of uremia in nephritis, but vomiting is also frequent at this stage and is a very potent cause for such low levels. In a selected group of patients[8] who had advanced nephritis but who were not vomiting, the plasma fixed base values fell between 145 and 152 milliequivalents per liter; normal values with the same technique fell between 148 and 155. This slight difference, while hardly significant, might well be a diuresis effect. These patients had a polyuria and relatively few surviving nephrons. Consequently the rapid rate of tubular flow should have offered some handicap to tubular reabsorption.

If depressed levels of plasma fixed base result from the excretion of acid which would normally be carried off by ammonia, then prolonged administration of acid should have a very pronounced effect in lowering these levels in nephritis. Such, however, is not the case. In the studies of Linder,[9] Gamble, Blackfan, and Hamilton,[10] as well as that of my own,[8] there was no significant change in the level of plasma fixed base, in either normal or nephritic subjects as a result of heavy dosage of acid. This is one of the most important observations relating to the question of base waste in nephritis.

In certain instances an excessive amount of fixed base has been found to be excreted into the urine of nephritic patients as a result of acid administration. The urinary excretion of the various acids and bases was determined in each of the above-mentioned studies of acid ingestion. Gamble and co-workers observed that excretion of extra fixed base by their nephritic patient was excessive in comparison with their normal controls. However, this was a patient with an edematous type of nephritis, and so the significance is uncertain—delivery of edema fluid from any cause should result in the elimination of extra fixed base. Linder's study gave complete results on two nephritic subjects without edema. One excreted an excessive amount of fixed base, while the other did not. In my own study one of three nephritic subjects excreted an excessive quantity of fixed base, but this was accompanied by a conspicuous diuresis—twenty-four-hour urine volumes greater than 3,000 c.c.

The evidence for impaired conservation of fixed base in nephritis is certainly inconclusive, and the incrimination of the defective ammonia mechanism for such evidence as is available seems quite unnecessary.

THE EVIDENCE OF RECENT DEVELOPMENTS IN RENAL PHYSIOLOGY

The results of much critical study[11] tend to support the essentials of the "modern theory of urine formation," as elaborated by Cushny. The glomerular fluid seems to be a true filtrate which is formed, in an adult, at the rate of about 120 c.c. per minute. It also appears that the resultant fluid formed by reabsorption in the various compartments of the tubule system must be of fairly constant composition, especially so in regard to the constituents of the basic elements; otherwise the levels of these constituents in the plasma would not be maintained within their observed narrow ranges. The tubules do, however, secrete a few substances. Perhaps the most important of these is ammonia, the secretion of which in the amphibian tubule has lately been reported by Walker.[12]

QUANTITATIVE RELATIONS BETWEEN SECRETION OF AMMONIA AND REABSORPTION OF FIXED BASE

The notion that secretion of ammonia is necessary for reabsorption of fixed base probably rests on the failure to bear in mind the quantitative relations of the two processes. With glomerular filtration at the rate of approximately 120 c.c. per minute, and with a fixed base concentration of about 150 meq. per liter, something like 1,080 meq. per hour of fixed base is filtered. Consequently, with the urinary excretion of fixed base at levels varying from 2 to 20 meq. per hour, the magnitude of fixed base reabsorption is seen to be at the enormous level of more than 1,000 meq. per hour. Under ordinary conditions the output of ammonia amounts to something less than 3 meq. per hour. It is, therefore, perfectly clear, when the magnitudes of these two processes are contrasted, that reabsorption of fixed base does not depend on substitution of ammonia. The highest levels of ammonia production, such as those observed in diabetic acidosis, are of the order of 25 meq. per hour, and so even these are hopelessly inadequate in accounting for fixed base reabsorption. The comparison is somewhat improved by making an additional assumption, which would bestow on the renal epithelium the capacity for differentiating between the base opposed by bicarbonate and the base opposed by chloride and other strong acid; ammonia to be substituted only for base opposed by bicarbonate. But this fraction of the total fixed base amounts to nearly 200 meq. per hour, which is again far greater than the maximum observed levels of ammonia production.

WORK ON THE ISOLATED NEPHRON OF AMPHIBIA

This work has been done on material aspirated directly from various levels of the tubule. In the proximal tubule there is no secretion of ammonia,[12] but glucose is reabsorbed and presumably along with it a considerable amount of water and salt.[13] The fixed base of this salt is therefore reabsorbed without substitution of ammonia. Actually ammonia was not found to appear before the distal half of the distal convoluted tubule, but chloride was actively reabsorbed by the first part of the distal tubule, and without change in pH,[14] so it must have been accompanied by an equivalent quantity of fixed base. Reabsorption of additional fixed base is thus accomplished without substitution of ammonia.

Acidification of the urine was observed to occur in a narrow zone near the middle of the distal tubule. The process of acidification was thought to depend on reabsorption of base bicarbonate. Since it was at this zone of acidification that secretion of ammonia was found to be initiated by Walker,[12] it is of great interest to speculate on the relation of the two processes. It is evident that ammonia is not substituted for all the base bicarbonate reabsorbed in this zone, for if so there would be no acidification. The manner in which ammonia is usually thought to operate is by interaction with salts of the glomerular fluid according to the reversible equilibrium:

$$NH_4HCO_3 + BAc \rightleftharpoons NH_4Ac + BHCO_3$$

According to this scheme, base bicarbonate would be reabsorbed and the acid radical would be carried off into the urine as ammonium salt.[11] But ammonia has been observed to be secreted only in the presence of acid.[12] Consequently, such a reversible equilibrium could never get anywhere in either direction because of the vigorous interaction of ammonia with acid, already liberated according to the scheme:

$$NH_4HCO_3 + HAc \rightarrow NH_4Ac + H_2CO_3$$

This reaction would very rapidly be carried to completion because of the slightly dissociated character of H_2CO_3.

Since ammonia reacts with acid which results from reabsorption of base bicarbonate, it might be said that the arrival of ammonia, unfortunately, is too late for the rescue. The simultaneous appearance of ammonia and acid formation is, to say the least, suggestive that secretion of ammonia operates as a local protective mechanism to prevent excessive acidity.

STUDIES OF THE MAMMALIAN NEPHRON

Preliminary reports from two separate laboratories[15, 16] each indicate that reabsorption of bicarbonate, that is acid production, may occur in the proximal tubule of the mammalian nephron. If this is true, it means there can only be a limited field of action for interchange of ions between ammonium bicarbonate and salts of the glomerular filtrate—even if secretion of ammonia should be found to occur at a level above the zone of acidification. If, as in Amphibia, secretion of ammonia is initiated at the zone of acidification, then the interpretation will be that indicated above; the classical concept relating secretion of ammonia to conservation of fixed base will have to be radically revised.

SUMMARY AND CONCLUSIONS

Crucial experiments show that ammonia production can, at will, be made to fluctuate in a direction opposite to that of any given acid-base change in the body. In all such experiments ammonia production fluctuates in the same direction as the acid-base change of the urine.

With advanced nephritis, in spite of curtailed production of ammonia, there is no clear-cut evidence of impaired conservation of fixed base. The evidence which is available does not necessarily incriminate the ammonia mechanism. Other factors, such as vomiting or diuresis, are usually present in instances of defective base conservation.

Examination of fluid taken from various levels of the amphibian nephron reveals that secretion of ammonia *follows* reabsorption of fixed base; and that ammonia is only secreted in the presence of acid, which precludes an interchange of ions in the reversible equilibrium usually assumed to be involved in the substitution of ammonia for fixed base.

It, therefore, seems improbable that the renal ammonia mechanism has anything to do with the regulation of the acid-base balance of the body. The evidence at hand appears to be more consistent with the hypothesis that secretion of ammonia is stimulated by, and serves to neutralize, the acid residue left in the tubules by reabsorption of the alkaline threshold moiety.

BROMSULPHALEIN RETENTION IN LOW-GRADE CHRONIC ILLNESS

MAJOR M. H. STILES, M.C., U. S. ARMY, M. T. STILES, AND A. McM. KOLB
PHILADELPHIA, PA.

LIVER dysfunction has been reported associated with a variety of chronic or recurrent conditions; e.g., allergy,[1-4] "rheumatism" and arthritis,[5-11] peptic ulcer,[12] glaucoma,[13] Parkinsonism,[4] thyrotoxicosis,[14-17] rheumatic fever,[18] various infections and bacterial intoxication.[4, 12, 19-23] Because of these reports liver function studies were made on a group of patients with low-grade chronic illness probably secondary to chronic infection.

The clinical condition, sedimentation rate, and nonfilament-filament ratio,[24, 25] incidence of probable pathogenic streptococci and staphylococci[26] and distribution of metabolic rates[27] of this group have been reported. One hundred and twelve ambulant patients, varying in age from 15 to 82, were included. They were classified according to age, sex and the severity of objective symptoms.

In the choice of a method for determining liver function the bromsulphalein test was considered favorably, since it could be performed in an office on ambulant patients, it did not consume much of the patient's time, and it was considered by many to be the most generally satisfactory test in the absence of jaundice.[28-31] However, while some[32, 33] felt that the usual bromsulphalein test was very sensitive and would indicate early, and perhaps even temporary liver dysfunction, others[5, 34, 35] felt that it was necessary to devise an even more delicate test for use in mild cases. Macdonald,[36, 37] who studied this question intensively, pointed out that because of the great liver reserve a normal result with the usual bromsulphalein test did not indicate an absence of hepatic damage, although an abnormal retention almost definitely meant a diseased liver. Studying liver reserve in the search for a test which would detect minor grades of impairment, he developed a technique by means of which the blood could be examined at two-minute intervals following the injection of bromsulphalein. With this method he observed that the rate of bromsulphalein removal from the blood of normal persons followed a definite curve, and that disease of the liver produced not only a retention of bromsulphalein beyond the usual test period, but also a change in the type of curve. As a result of his observations Macdonald concluded that a quantity of bromsulphalein equivalent to 5 mg. per kilogram of body weight was necessary to test fully the liver reserve, that the normal undamaged liver would completely free the blood of this quantity of bromsulphalein in twenty-five minutes, and that the maximum information about liver function would only be obtained if the blood level of bromsulphalein were determined every five minutes. In a recent

Received for publication, July 11, 1942.

evaluation of liver function tests Mateer and his colleagues[38] found Macdonald's serial bromsulphalein test sensitive and reliable, even though the 2 mg. per kilogram dose was mainly used. Suggestions for fractional tests of liver function have also been made by White, Deutsch, and Maddock,[39] and by Deutsch.[40]

TABLE I

STATISTICAL ANALYSIS OF BROMSULPHALEIN RETENTION DISTRIBUTED ACCORDING TO SEX, AGE, SEVERITY OF SYMPTOMS AND SEDIMENTATION RATE

GROUP	NO.	RANGE	MEAN	±	S.E.	% 0	% 5-20	% 20+
All patients	112	0-90	18.93	±	1.63	14.3	56.3	29.3
Sex								
Male	45	0-70	19.33	±	2.45	15.6	51.1	33.3
Female	67	0-90	18.66	±	2.18	13.4	59.7	26.9
Age								
Up to 20	9	0-60	18.33	±	5.84	11.1	66.6	22.2
21-40	27	0-50	12.78	±	2.4	25.9	52.0	22.1
41-60	49	0-90	17.96	±	2.54	12.2	65.4	22.4
61+	27	0-70	27.04	±	3.4	7.4	40.8	51.8
Symptoms								
Mild	48	0-30	10.0	±	1.19	22.9	70.9	6.2
Moderate	47	0-50	18.94	±	1.83	10.6	53.2	36.2
Severe	17	5-90	44.71	±	5.25	0.0	23.5	76.5
Sedimentation rate in mm. (Westergren)								
1-10	59	0-50	14.75	±	1.71	20.4	57.5	22.1
11-20	28	0-90	20.71	±	3.89	10.7	57.1	32.2
21-30	13	0-60	22.31	±	4.68	7.7	53.9	38.4
31+	8	5-70	32.50	+	7.39	0.0	37.5	62.5

No. = Number of patients in group. Range = range of bromsulphalein retention in units. S.E. = Standard error. % 0 = per cent of patients in group with no bromsulphalein retention. % 5-20 = per cent with 5 to 20 units retention. % 20 + = per cent with more than 20 units retention.

In the present study Macdonald's normal criterion of complete elimination in twenty-five minutes of a dose of bromsulphalein equal to 5 mg. per kilogram body weight was adopted. The estimated quantity of bromsulphalein solution diluted with an equal quantity of physiologic salt solution was slowly injected with a No. 26 gauge needle. For simplicity usually only a single specimen of blood was withdrawn twenty-five minutes later. The use of larger needles and of full strength bromsulphalein solution in early tests was occasionally followed by thrombophlebitis, which in one instance was moderately severe and resulted in several days' incapacitation.

RESULTS

A statistical analysis of the results of the bromsulphalein tests is presented in Table I. Of the 112 patients only 16 showed no retention of bromsulphalein at the end of twenty-five minutes. If the blood had been examined at five-minute intervals throughout the test period, it is probable that even some of these would have shown abnormal curves.[41] Somewhat more than half of the total number showed bromsulphalein retention of from 5 to 20 units. The remaining patients showed higher degrees of retention, the highest being 90 units. The mean value for the entire group was 18.9. The frequency distribution of the tests is illustrated in Fig. 1.

When the observations were distributed according to sex, very little difference was found, the mean bromsulphalein retention being 19.3 units for males and 18.7 units for females (Fig. 2). When the observations were distributed according to age, greater differences were noted (Fig. 2). The mean bromsulphalein retention in units for patients up to 20 was 18.3; 21 to 40, 12.8; 41 to 60, 17.0; and 61 and over, 27.0. The mean rates for patients 21 to 40, and for those 61 and over, varied significantly from the mean of the entire group.

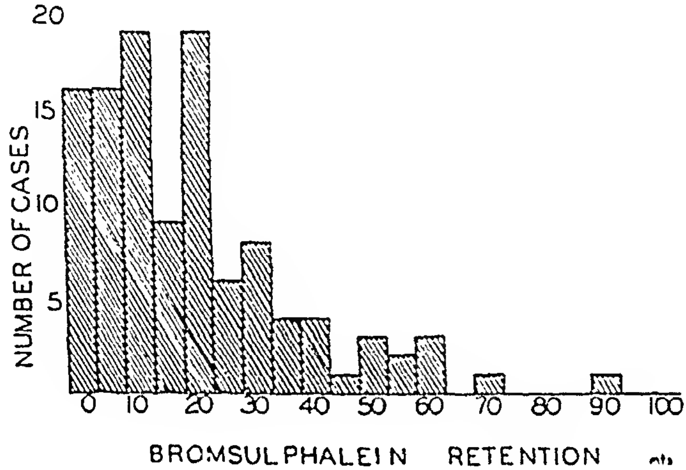

Fig. 1.—Frequency distribution of bromsulphalein retention in 112 patients with low-grade chronic illness.

When the observations were distributed according to the severity of symptoms (Fig. 3), greater differences appeared. The mean bromsulphalein retention in patients with mild symptoms was 10 units; in patients with moderately severe symptoms, 18.9 units; and in patients with severe symptoms, 44.7 units. Of the patients with mild symptoms 22.9 per cent showed no retention of bromsulphalein and only 6.2 per cent showed retention of more than 20 units. Of those with severe symptoms all showed some retention and 76.5 per cent showed retention of more than 20 units.

Since it has been suggested that there may be a relation between liver function and the sedimentation rate of erythrocytes,[42] the bromsulphalein retention and the sedimentation rate (Westergren) were compared (Fig. 4). The mean bromsulphalein retention for patients with sedimentation rates, ranging from 1 to 10 mm., was 14.75 units; 11 to 20 mm., 20.7 units; 21 to 30 mm., 22.3 units; and over 30 mm., 32.5 units. Yet, while in general higher sedimentation rates were associated with higher degrees of bromsulphalein retention, the association was far from complete. For example, in patients with sedimentation rates up to 10 mm. the degree of bromsulphalein retention varied from 0 to 50 units, and in those with sedimentation rates of 31 mm. or higher it varied from 5 to 70 units. The lack of a definite linear relation between sedimentation rate and bromsulphalein retention is illustrated by the scatter diagram in Fig. 5.

The differences between the mean bromsulphalein retention rates of patients with mild, moderately severe, and severe symptoms were all statistically significant, as were also the variations in relation to changes in sedimentation rate.

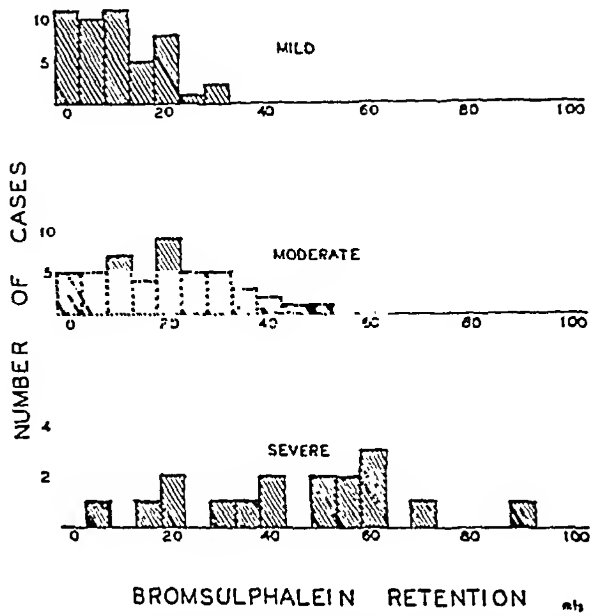

Fig. 2.—Bromsulphalein retention distributed according to sex and age.

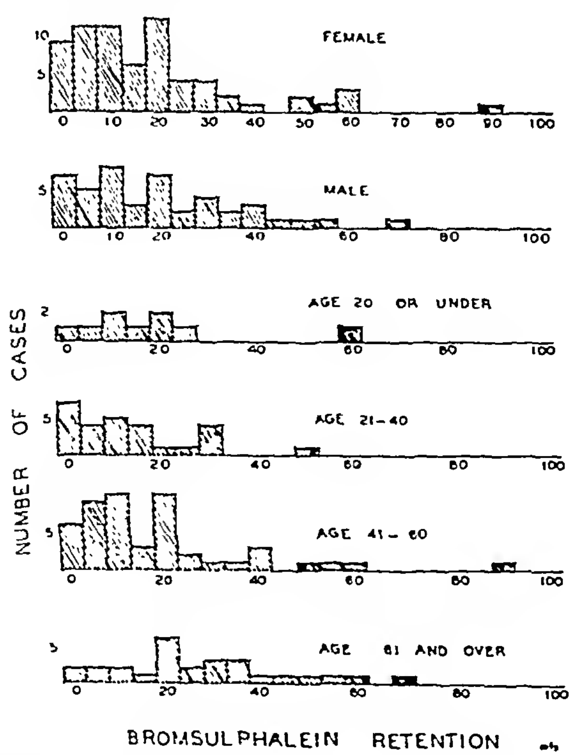

Fig. 3.—Bromsulphalein retention distributed according to severity of general symptoms.

COMMENT

The high incidence of impaired liver function in persons with chronic illness should not cause surprise if the reports of earlier writers are recalled. Rehfuss[43] has stated that biliary tract disturbance is probably present in one half of all persons past the age of 40. MacLagan and Rundle[17] stated that of 41 patients with hyperthyroidism, 30 showed definite impairment of hepatic function and the remaining 11 were border line. Shaffer,[16] in examining the livers of persons who died accidental deaths, found that 31 of 50 showed fatty infiltration, and 11 of 50 showed chronic localized interstitial hepatitis. Rosenberg[44] used the cephalin-cholesterol flocculation test in studying a group of 155 persons of whom 83 had clinical evidence of liver disease. He found liver impairment in practically all of those with clinical liver disease and in 43 of

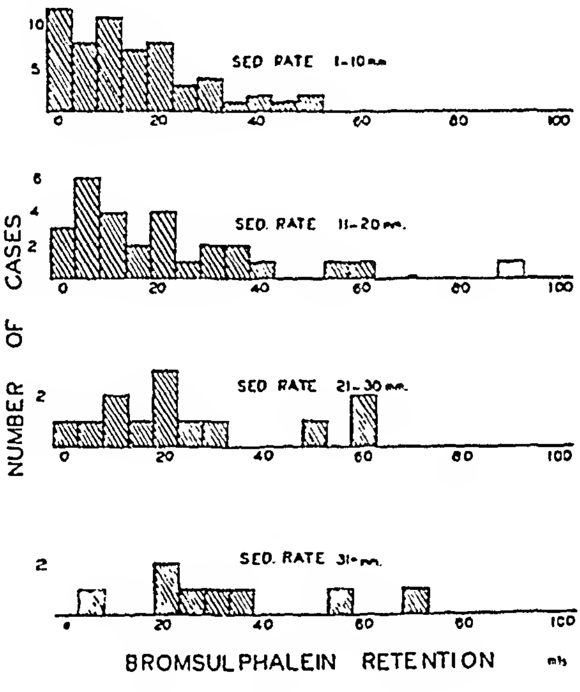

Fig. 4.—Frequency distribution of bromsulphalein retention in relation to sedimentation rate.

the 72 in whom hepatic disease was not suspected. He concluded that mild and subclinical disease of the liver occurs more frequently than is generally appreciated, and unless specifically sought may elude recognition. Apparently liver disturbance is frequent even in early life, since Londe and Probstein[45] found evidence of disturbed liver function in two children whose only departure from health had been recent upper respiratory infections, and in 9 of 13 children with histories of repeated colds. These findings are consistent with the observations made in the present study, where 8 of 9 children and adolescents showed some degree of bromsulphalein retention.

While the variations in bromsulphalein retention in relation to age are statistically significant, their actual significance is somewhat impaired by the high proportion of patients with mild symptoms in the age group 21 to 40, and

the high proportion with severe symptoms in the age group 61 and over. It may be significant that in the series of studies which have been made on patients with low-grade chronic illness,[24, 26, 27] the group from 21 to 30 years of age showed fewer deviations from the normal than did any other group.

The variations in bromsulphalein retention in relation to severity of symptoms also are consistent with the observations made in other studies of low-grade chronic illness. Patients with mild symptoms showed the least deviation from normal in the sedimentation rate,[24] the nonfilament-filament ratio,[24] the incidence of pathogenic streptococci,[26] and in the basal metabolic rate;[27] and persons with severe symptoms showed the greatest deviation from normal in all of these tests. Rawls, Weiss, and Collins[8] noted that liver dysfunction occurred with greater frequency in patients with severe than in those with mild rheumatoid arthritis.

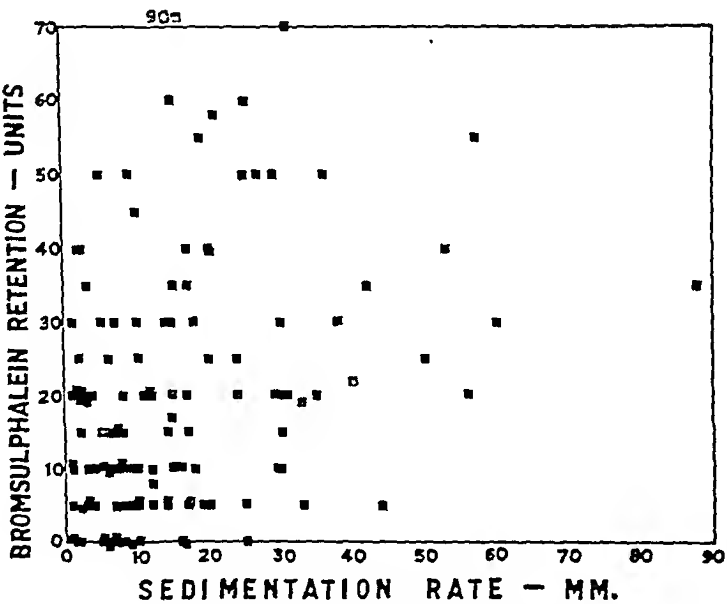

Fig. 5.—Relation of bromsulphalein retention (units) and sedimentation rate (mm. in one hour, Westergren) in individual patients.

While patients with high sedimentation rates had significantly greater bromsulphalein retention than did those with low sedimentation rates, it is possible that abnormal results with both tests are related more to the severity of illness than to each other. In view of the high degree of bromsulphalein retention occasionally associated with a practically normal sedimentation rate, and the high sedimentation rates associated with little bromsulphalein retention, there does not seem to be a direct relation between the two tests. It is possible, of course, that some other test of liver function might give results more nearly parallel to the sedimentation rate. It seems more probable, however, that, as Wintrobe[46] has said of the sedimentation rate, neither the sedimentation rate nor the bromsulphalein retention should be regarded as a precise, quantitative measurement, but should be accepted as a general indication of somatic or hepatic disturbance.

SUMMARY

Studies of bromsulphalein retention were made on 112 patients with low-grade chronic illness, using a dose of 5 mg. per kilogram of body weight.

On the basis of Macdonald's criterion of normal excretion all but 16 showed evidence of liver dysfunction. Of the 96 with dysfunction 33 showed more than 20 units retention of bromsulphalein.

The mean bromsulphalein retention of males differed little from that of females. The mean retention of patients aged 21 to 40 years was less than the general average and that of patients over 60 was greater, but the actual significance is uncertain.

When the mean bromsulphalein retention of patients with mild general symptoms was compared with the mean retention of patients with moderately severe and severe symptoms, statistically significant differences were found, the respective values being 10.0, 18.9 and 44.7 units.

While patients with high sedimentation rates tended to have a high degree of bromsulphalein retention, there were a number with high rates who had little retention, and a number with low rates who had considerable retention.

CONCLUSIONS

Impairment of liver function is found in a considerable proportion of patients with low-grade chronic illness.

The degree of impairment varies directly with the severity of symptoms.

SOLUBILITY AND pH DATA OF SOME OF THE COMMONLY USED SULFONAMIDES*

William G. Clark, Ph.D., Ernest A. Strakosch, M.D., M.S., and Nathan I. Levitan, M.S., Minneapolis, Minn.

While working in the field of the local application of sulfonamides to infections, we frequently needed solubility and pH data of the sulfonamides. A search of the literature has failed to reveal a source of collected data on these physical properties of the more commonly used sulfonamides. The data which exist are very scattered and frequently appear in papers which are abstracted in such a way as to disguise the fact that such data do appear in the papers. Moreover, some data are lacking in the literature we have been able to examine, including brochures and pamphlets of various commercial firms.

Hence it was thought that if these data were made available in collected form in a single table, it would prove extremely useful to workers in the fields of chemotherapy, particularly at the present time. For this reason, we have determined the solubilities of the commonly used sulfonamides and their sodium salts at room temperature and at body temperature in water and in human serum. In addition, we have determined the pH values of the saturated aqueous solutions, since this information is also lacking in many instances.

EXPERIMENTAL

A small tinted glass container containing excess sulfonamide in carbon dioxide-free distilled water or in serum, was shaken in a water bath thermostatically controlled to within 0.1° C. for twenty-four hours. The saturated solution was then filtered by aspiration through a washed and dried asbestos filter stick into a weighed weighing bottle. The entire apparatus was kept at the temperature at which the compound was dissolved (25° C. or 37° C.). The amount dissolved was then determined by the method of Bratton and associates,[1] using a photoelectric colorimeter. The pH values in carbon dioxide-free distilled water were determined at 25° C. with a Coleman pH meter (glass electrode/calomel electrode). The results are tabulated in Table I, along with values collected from the literature by other workers.

The large difference in solubility of sulfathiazole and sulfadiazine in water versus serum are striking, especially the latter. It has been pointed out by Roblin and others,[8] that blood levels exceed the solubility of sulfadiazine in water, while the blood levels obtained with the other sulfonamides are below the water solubility.

*From the Division of Physiology, Department of Zoology, and the Division of Dermatology and Syphilology, University of Minnesota, Minneapolis.

Supported by grants from the General Research Fund of the University of Minnesota, and the Abbott Laboratories, North Chicago, Ill. Assistance was furnished by the personnel of Work Projects Administration, O.P. 165-1-71-124, Subproject 383.

Received for publication, July 15, 1942.

TABLE I

SOLUBILITY AND pH DATA OF SOME OF THE COMMONLY USED SULFONAMIDES
(% = grams per 100 Gm. of the solvent)

Compound	25° C. Temperature					37° C. Temperature			
	Water (%)	Human Serum (%)	pH*	Refs.	Remarks	Water (%)	Human Serum (%)	Refs.	Remarks

FAT METABOLISM IN ACNE VULGARIS*

Edward B. LeWinn, M.D., and I. Zugerman, M.D.
Philadelphia, Pa.

WHILE the relationship between fat metabolism and acne vulgaris has been suggested previously,[1] no studies of this problem have been made by methods which reflect the status of the fat metabolism in this skin disease. It has also been proposed that acne vulgaris is of endocrine origin, but up to the time of the present report the investigations have been disappointing, the results permitting no certain conclusions. Cholesterol is chemically related to the steroidal hormones, such as estrogens and androgens, the latter having been found to cause acne when given to women in very large doses.[2] On the other hand, cholesterol is intimately associated with the metabolism of fats. This dual relationship was utilized in a study of fat tolerance in acne vulgaris, herein reported, employing the blood cholesterol as an indicator of the blood lipid content.[3]

MATERIAL

In this investigation 20 patients, 12 females and 8 males, with acne vulgaris were studied. Their ages ranged from 11 to 29 years, the average being 19 years. The duration of their acne varied from one month to 11 years. The severity of the lesions varied from a few well-marked comedones and pustules on the forehead to extensive and active involvement of the forehead, face, shoulders, chest, and back. Most of the 12 female patients exhibited some menstrual disturbances, mainly irregularity or amenorrhea.

Thirteen patients without evidence of past or present acne were studied for comparison with the acne patients. These patients also served as controls in a study of fat metabolism in psoriasis.[3] There were 8 women and 5 men in the group, ranging in age from 20 to 65 years, the average being 41 years. The average age of the control group is considerably higher than that of the acne patients. However, advancing age causes only very slight changes in blood cholesterol levels.[4]

PROCEDURE

After a twelve-hour fast a blood specimen was taken. The patient then drank 500 c.c. of 20 per cent cream, representing 100 Gm. of fat. Blood specimens were then obtained at intervals of one and one-half, three, four and one-half, six, and seven and one-half hours, and the whole blood was examined for total cholesterol by the method of Bloor.[5] During the time of the test each patient was allowed to take an occasional sip of water. Most patients were ambulant but activity was closely restricted.

---

*From the Medical Service of Dr. Mitchell Bernstein and the Dermatological Service of Dr. A. Strauss, Jewish Hospital, Philadelphia.

Received for publication, August 7, 1942.

RESULTS

The fasting total cholesterol levels in 20 cases of acne vulgaris were between 125 mg. and 275 mg. per 100 c.c. of whole blood, the mean being 173 mg. In the 13 control cases the fasting cholesterol ranged from 123 to 250 mg. per 100 c.c.,

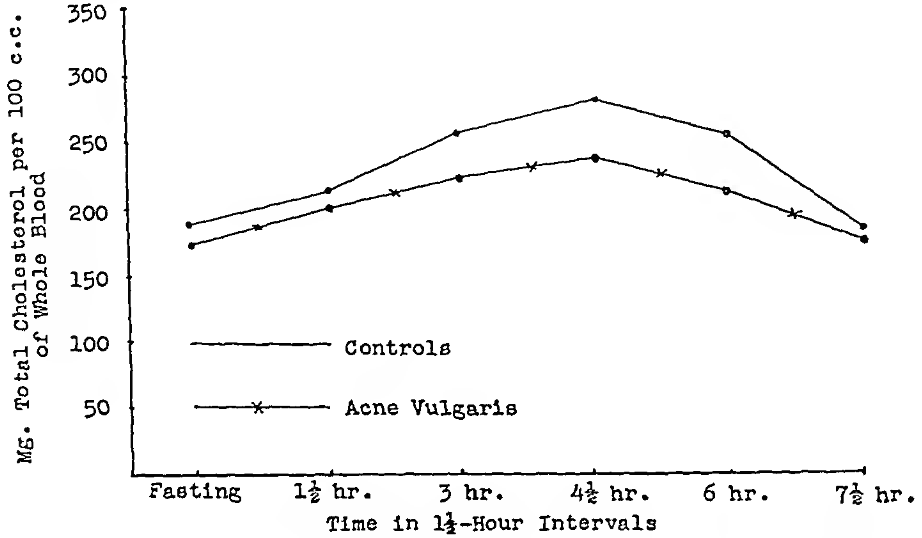

Fig. 1.—Composite blood cholesterol curves following the ingestion of fat.

the mean being 188 mg. In the acne patients the range of increases from fasting to the highest level of blood cholesterol was from 25 mg. to 208 mg. per 100 c.c. of whole blood, the mean being 83 mg. On the other hand, the control group showed increases above the fasting level of from 42 mg. to 198 mg., with a mean of 119 mg. (Table I).

TABLE I

PATIENTS WITH ACNE VULGARIS

CASE	FASTING	1½ HR.	3 HR.	4½ HR.	6 HR.	7½ HR.	MG. RISE

17	208	250	312	416	208	178	208
18	227	263	295	333	250	192	106
19	250	333	257	455	357	312	205
20	275	257	312	227	184	166	82

Data for control patients have been presented in an earlier publication.[3]

Examination of the curves of the means of the two groups does not reveal a significant difference between them in fat tolerance, all points of the composite curves of both groups being within accepted normal limits. The marked similarity between the acne and the nonacne patients is further emphasized by statistical examination of the figures. The application of the *t* test to the fasting levels of blood cholesterol gives a value of 0.3. The value of *t* for the peak levels of the two groups is 0.6. For groups of the size studied in this report *t* should have a value of 2.04 or greater to be considered significant. It is worthy of note that Strickler and Adams[6] were also unable to demonstrate any departure from normal in the fasting blood cholesterol levels of acne patients.

CONCLUSIONS

A study of the fat tolerance, as indicated by blood cholesterol changes following the ingestion of fat, of a group of 20 patients with acne vulgaris fails to reveal any difference from a group of patients without acne vulgaris.

Dr. E. D. Burdick, of the University of Pennsylvania, assisted in the statistical review of our results.

Dr. O. E. Helm, Jr., permitted us to study several of his patients in the Dermatological Service at Frankford Hospital.

LABORATORY METHODS

GENERAL

A MODIFICATION OF THE KAHN TEST FOR USE WITH HEMOLYZED BLOOD*

H. J. LAWLER, Sc.D., ST. LOUIS, MO.

IN LABORATORIES which perform diagnostic tests for syphilis, one difficulty is that presented by blood specimen that has undergone so much hemolysis that precipitation tests cannot be read. The physician is usually notified that the specimen is not suitable for diagnostic test, and he is asked to send another sample of blood. There is inconvenience to both physician and patient.

Some idea as to the frequency of such hemolyzed specimens may be gained from the following tabulation of the last two years' experience of the St. Louis City Bacteriological Laboratory, where Kahn tests are performed on blood specimens collected by messenger from various points throughout the city each evening and tested the day after the blood is drawn.

	1940	1941
Total number of Kahn tests run	55,518	74,918
Number hemolyzed	343	689
Percentage hemolyzed†	59	91

The sharp increase in the number of hemolyzed specimens in the latter year is probably related to the fact that many of the specimens submitted in connection with the selective service physical examinations were drawn by physicians who had previously had relatively little experience with the submission of specimens to the municipal laboratory. Those physicians who send them in frequently are apparently more aware of the precautions which aid in the prevention of hemolysis.

When the percentages of hemolyzed specimens received by the laboratory are graphically represented in relation to the months of the year, as in Fig. 1, it is apparent that the problem is accentuated during the summer months. This was particularly true during 1941, when approximately four such specimens were received by the laboratory each working day from May through September.

*From the Department of Bacteriology and Immunology, Washington University School of Medicine, St. Louis.

†Included as hemolyzed are those specimens containing enough hemoglobin to obscure completely the reading of the Kahn test.

Received for publication, April 24, 1942.

The best solution of the problem would be the prevention of hemolysis, and much of it can be prevented by reminding the physician of the simple precautionary measures:

a. Use of a dry syringe and a fairly large needle.
b. Permit the blood to flow into the syringe, with a minimum of negative pressure.
c. Remove the needle from the syringe before *gently* emptying the syringe.
d. If feasible, place the specimen in a refrigerator, especially if there may be delay in getting it to the laboratory.

If, however, hemolyzed specimens are sent in, then the laboratory might well make use of them if adequate modification of existing methods is made available to assure the reliability of such tests. Any satisfactory method should remove the hemoglobin, should give the same results that would have been obtained with clear serum from the same source, and should be adapted to the equipment and skills of the usual public health laboratory.

The particular method described herein is essentially a modification of the usual Kahn test for spinal fluid. The serum is diluted with a relatively large volume of ammonium sulfate solution to "salt" out the globulin; this is centrifuged to a minimum volume. The supernatant solution, containing most of the hemoglobin of the original specimen, is poured off, the globulin is redissolved, and a slightly modified Kahn test is performed on the globulin solution.

MATERIALS AND METHODS

Syphilitic sera for testing the efficiency of the proposed method were obtained from the St. Louis City Bacteriological Laboratory. Only weakly positive and negative sera were used, for it was found that strongly positive sera gave uniformly positive tests even with less adequate modifications of the method and, therefore, could not be used in comparative evaluations. "Hemolyzed specimens" were prepared from these sera by the addition of "hemoglobin solution" prepared in the following manner: Packed red blood cells from nonsyphilitic blood were alternately frozen and thawed until hemolyzed. After removal of stroma by centrifugation, the resulting serum was adjusted to contain 20 Gm. of hemoglobin per 100 ml., as determined by the cyanmethemoglobin method in the Evelyn colorimeter (Evelyn and Malloy, 1938), and 0.2 ml. of this "hemoglobulin solution" was added to 0.8 ml. of serum of known syphilitic titer to produce 1 ml. of a hemolyzed specimen. These proportions were determined by estimation that hemolysis sufficient to obscure completely the Kahn precipitate might add 20 per cent to the volume of the serum.

The Kahn tests were performed in the manner prescribed by Kahn (1928). They were read immediately after the addition of saline, and again after fifteen minutes; the amounts of precipitate in the three tubes are expressed in the tables in this paper in terms of plus signs. The results of the second reading are recorded above the results of the first, if there was any change.

PREPARATION OF GLOBULIN SOLUTION

1. The specimen is subjected to centrifugation to remove cells, clot fragments, etc., as in the usual preparation of serum (fifteen minutes at 2,000 r.p.m.).

2. One milliliter of the supernatant fluid is pipetted off into a small round-bottomed test tube (the 100 by 12 mm. size is convenient), and after addition of 5 ml. of ammonium sulfate solution* the mixture is incubated at 56° C. for fifteen minutes.
3. The precipitate which is formed is separated by centrifuging at 2,000 r.p.m. for twenty minutes. Supernatant fluid is poured off, and the tube containing the precipitate is inverted over absorbent paper to remove as much of the salt solution as is convenient.
4. The sediment in the tube is dissolved by the addition of 1.3 ml. of distilled water, while stirring with a wooden applicator stick, and after centrifuging for five minutes at 1,500 r.p.m., the supernatant is transferred into another tube by means of a capillary pipette.
5. Three tube Kahn test is now set up, using 0.15 ml. of this globulin solution (instead of serum) and the usual amounts of antigen (Kahn, 1928) in each tube. The mixture is shaken at the rate of 275 times per minute for *four* minutes instead of three.

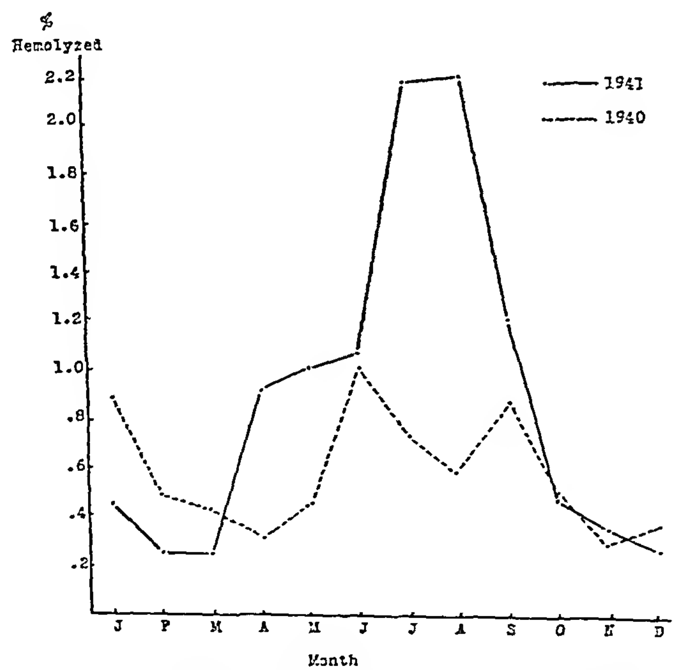

Fig. 1.—The occurrence of hemolyzed specimens among those received during 1940 and 1941 by the St. Louis Municipal Bacteriological Laboratory.

The reliability of this procedure was tested by using it with (a) "hemolyzed specimens" prepared as outlined previously, and (b) similar specimens were prepared by the addition of negative serum to the syphilitic sera in place of "hemoglobin solution." In Table I are listed the results of such tests, along with the results of standard Kahn tests run simultaneously on twenty-four different sera.

In general, these comparative tests showed good agreement between the standard Kahn and the modified test with globulin solution; the greatest varia-

*The solution is prepared by adding 48 Gm. of "analytical reagent" grade ammonium sulfate to 100 ml. of distilled water. In adding this to the serum, blowing it in is an easy method of mixing.

tion between the two in the case of any one serum was ++. The reagin-antigen precipitates were slightly smaller when formed from the globulin solution than when formed from whole serum, although the recommended extra minute's shaking given the antigen-globulin mixture tends to make this difference less pronounced.

An additional observation, possibly bearing on the evaluation of the modified test, was made in the case of globulin prepared from known negative sera: doubtful reactions (±) were frequent, and one-plus precipitates were formed in the middle tube in several cases. The particles of these precipitates were smaller and more evenly distributed than the usual Kahn precipitates.

FACTORS AFFECTING THE MODIFIED TEST

1. The amount of fluid used in dissolving the globulin.

Using four "hemolyzed specimens," prepared as outlined previously, parallel modified Kahn tests were run on solutions of globulin made by the addition of 0.8, 1.0, 1.2, and 1.4 ml. of 0.9 per cent saline solution to the precipitates. The results of these tests and of the simultaneously run standard Kahn tests on the original sera (Table II) showed the closest correspondence in the case

of the solution made with 1.2 ml. of saline. More than that amount (1.4 ml.) seemed to make the test less sensitive, while less (1.0 ml.) made it more sensitive, negative serum number 5 showing a doubtful positive. Still less produced bizarre reactions (see Table II).

2. The effect of increased amounts of hemoglobin.

Four sets of "hemolyzed specimens" were prepared, containing different amounts of "hemoglobin solution," as outlined in Table III. Modified Kahn tests on globulin precipitated from these gave results very similar to those obtained with standard Kahn tests on the sera; the added hemoglobin apparently interfered little, except in the case of the specimens prepared with 0.4 ml. of "hemoglobin solution." In these the second reading showed increases in the amounts of precipitate. In possible explanation of this it was noticed that the volume of the precipitated, centrifuged globulin in these tubes was about double that precipitated from those having only 0.1 ml. of "hemoglobin solution." The rest of the results, with specimens containing smaller amounts of "hemoglobin solution," so closely paralleled the control results that it seems likely the effect of hemoglobin on the globulin precipitation is probably small, within a rather wide range of concentration.

3. The ammonium sulfate solution.

It is recommended that "analytical reagent" grade of this salt be used, so that solutions used for globulin precipitation would be approximately the same regardless of the source of the chemical. In order to insure that the solution would be half saturated even at summer temperatures, it is made up with 48 Gm. added to each 100 ml. of distilled water. Five milliliters of this solution, plus 1 ml. of the serum from the hemolyzed specimen results in a solution that would be half saturated with ammonium sulfate at any temperature below 36° C.

SUMMARY

The problem of hemolysis in blood submitted to the St. Louis Municipal Bacteriological Laboratory is discussed. A method for performing a modified Kahn test on such "hemolyzed specimens" is described, and the results of comparative tests with this method and the standard Kahn test are given.

The modified Kahn test described herein for use with hemolyzed blood has been found to give approximately the same results as the standard Kahn test in comparative tests with a limited number of specimens. It is, therefore, being recorded with the view of suggesting comparative trial in laboratories which find hemolysis a definite problem.

I wish to express my gratitude to Dr. J. J. Bronfenbrenner and Mr. Nathan Nagle for advice and assistance in connection with the work.

Detroit, Mich.

The problem of redistilling two or three gallons of water every day can be troublesome when the largest flask available for a still has only the capacity of a liter. The use of a much larger flask is not satisfactory when only small burners are available for heating it. Accordingly, we devised the apparatus herein sketched to solve the problem. It permits continuous distillation throughout the day without, in our experience, requiring the slightest attention. A hasty survey of the literature plus consultation with our associates has failed to reveal a similar arrangement. Albeit, since the principles involved are so simple, they have undoubtedly been combined before to the same end. Hence, we make claim to nothing more than independent discovery. However, with the realization that other laboratories with limited apparatus may face a similar problem, we considered it worth while to make available a detailed description of the unit.

Essentially the siphon principle is combined with that of the Mariotte bottle. The bottom of the tube, *B*, in the Mariotte bottle, *A*, is adjusted so as to lie in the same horizontal plane as the surface of the water in the flask, *C*, when the flask has been filled to a level convenient for distillation. In practice the fluid usually rises somewhat higher in the flask *C* than the level calculated because the air in the Mariotte bottle *A* becomes progressively hotter as the distillation proceeds, due to the small amount of steam which bubbles back through the tube *D*. Accordingly, we usually adjust the Mariotte bottle, so that the end of the tube, *B*, is in the same horizontal plane as the surface of the liquid in the flask *C*, when the flask is about two-thirds full. The end of the siphon tube, *D*, is bent slightly upward and outward so that the orifice is near the wall of the flask. This tends to minimize the amount of steam which always bubbles back up through the tube, *D*, into the Mariotte bottle. Although this steam heats the water in the Mariotte bottles as the distillation progresses, in our experience this has neither interfered with the smooth operation of the unit nor cracked the nonpyrex Mariotte bottle. The lower opening of the tube, *D*, must, of course, be below the lower end of the tube, *B*, or the water will fail to siphon into flask *C*, as the distillation boils off the fluid in flask *C*. *H* is merely a plug of glass wool to prevent the entrainment of impure water droplets in the steam which passes over into the condenser, *E*. Any flask may serve as a receiver, *F*. *G* is a cotton plug to guard the opening of the receiver, *F*, so that no dust can fall into the receiver. The area of the condenser surface, if too small, will, of course, limit the rate at which one can distill since some of the steam, when too small a

THE problem of redistilling two or three gallons of water every day can be troublesome when the largest flask available for a still has only the capacity of a liter. The use of a much larger flask is not satisfactory when only small burners are available for heating it. Accordingly, we devised the apparatus herein sketched to solve the problem. It permits continuous distillation throughout the day without, in our experience, requiring the slightest attention. A hasty survey of the literature plus consultation with our associates has failed to reveal a similar arrangement. Albeit, since the principles involved are so simple, they have undoubtedly been combined before to the same end. Hence, we make claim to nothing more than independent discovery. However, with the realization that other laboratories with limited apparatus may face a similar problem, we considered it worth while to make available a detailed description of the unit.

Essentially the siphon principle is combined with that of the Mariotte bottle. The bottom of the tube, *B*, in the Mariotte bottle, *A*, is adjusted so as to lie in the same horizontal plane as the surface of the water in the flask, *C*, when the flask has been filled to a level convenient for distillation. In practice the fluid usually rises somewhat higher in the flask *C* than the level calculated because the air in the Mariotte bottle *A* becomes progressively hotter as the distillation proceeds, due to the small amount of steam which bubbles back through the tube *D*. Accordingly, we usually adjust the Mariotte bottle, so that the end of the tube, *B*, is in the same horizontal plane as the surface of the liquid in the flask *C*, when the flask is about two-thirds full. The end of the siphon tube, *D*, is bent slightly upward and outward so that the orifice is near the wall of the flask. This tends to minimize the amount of steam which always bubbles back up through the tube, *D*, into the Mariotte bottle. Although this steam heats the water in the Mariotte bottles as the distillation progresses, in our experience this has neither interfered with the smooth operation of the unit nor cracked the nonpyrex Mariotte bottle. The lower opening of the tube, *D*, must, of course, be below the lower end of the tube, *B*, or the water will fail to siphon into flask *C*, as the distillation boils off the fluid in flask *C*. *H* is merely a plug of glass wool to prevent the entrainment of impure water droplets in the steam which passes over into the condenser, *E*. Any flask may serve as a receiver, *F*. *G* is a cotton plug to guard the opening of the receiver, *F*, so that no dust can fall into the receiver. The area of the condenser surface, if too small, will, of course, limit the rate at which one can distill since some of the steam, when too small a

*From the Department of Pharmacology, Wayne University College of Medicine, Detroit. Received for publication, April 22, 1942.

condenser is employed, will pass over into the receiver uncondensed. In actual operation the distillation is started with water in flask *C*, at the usual level, about two-thirds full. As the water in *C* boils down to a critical level about one inch above the bottom of the flask, water begins to siphon over into the still, *C*, from the Mariotte bottle, *A*. This cool water stops the boiling until flask *C* is again about two-thirds full, at which point siphoning ceases. With each succeeding filling the water will rise to a slightly higher level in flask *C*, because the air in the

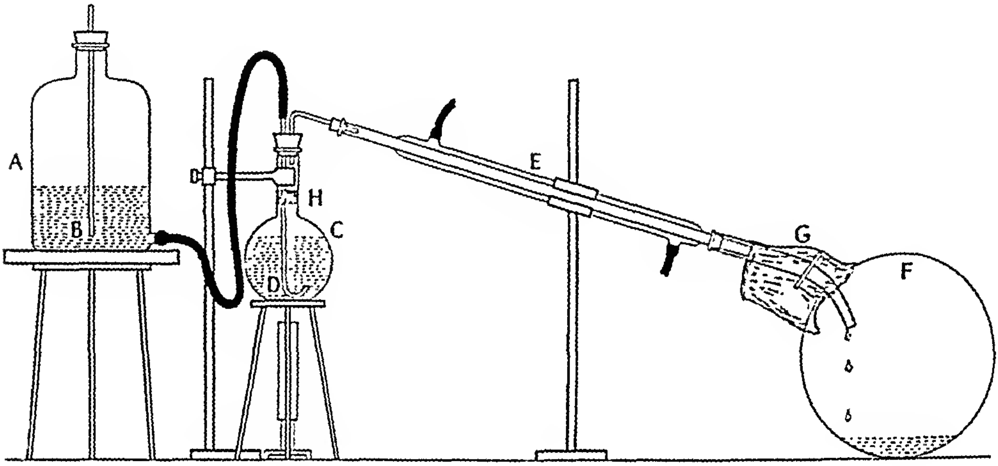

Fig. 1.

Mariotte bottle, as already noted, grows hotter as the distillation continues. All connections must be airtight and this precaution applies especially to the stopper in the top of the Mariotte bottle. With the precautions mentioned the distillation can be started early in the day and will smoothly proceed unattended as long as there is water in the Mariotte bottle. With our 10-liter Mariotte bottle it runs all day.

We offer this device in the hope it may prove of equal convenience to other laboratories faced with a similar problem. This arrangement is now being utilized by associates in other departments.

A METHOD FOR RAPID, REPEATED, APPROXIMATE DETERMINATIONS OF THE TRANSVERSE DIAMETER OF THE HEART

SAMUEL WALDMAN, M.D., BROOKLYN, N. Y.

THE routine determination of the transverse diameter of the heart is usually accomplished by means of teleoradiography, orthodiagraphy, and fluoroscopy.[1]

The teleoradiogram is the x-ray film of the heart, conventionally taken at a distance of six feet. This technique involves the use of x-ray equipment and x-ray film. In orthodiagraphy the examiner draws the outline of the heart in the visualized plane. This method requires much time and skill. With the fluoroscope, a direct examination is made, and contours can be studied in active motion.

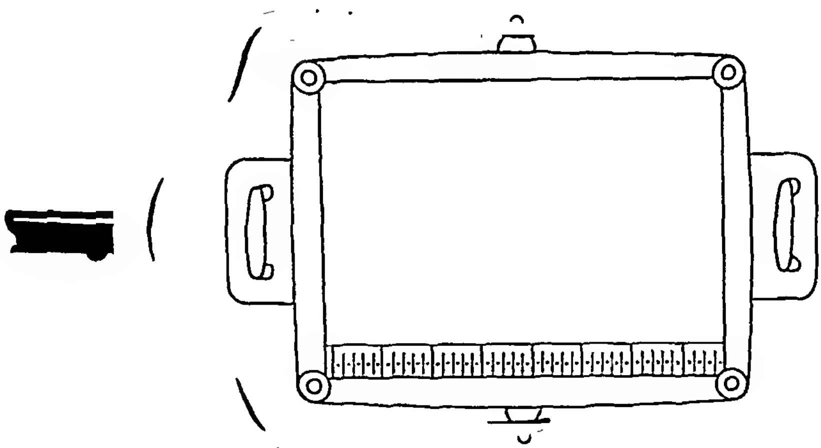

Fig. 1.

In order to determine rapidly and approximately the transverse diameter of the heart, I have devised a simple attachment to the fluoroscopic screen which, in a small degree, obviates the use of film and the orthodiagram, but which is not intended to supplant them.

For the conventional 12 by 16 inch fluoroscopic screen, a strip of x-ray film, ¾ by 16 inches, is cleared of emulsion by soaking in hot water. When it is thoroughly dry, lines are drawn on it with India ink as per diagram (Fig. 1). The width of the strip in the diagram is exaggerated for illustrative purposes. The ink is radiopaque and is easily seen during fluoroscopy of the chest. The complete lines indicate 5 cm., the incomplete lines 1 cm., and the dots 0.5 cm. Thus the accuracy is immediately limited to within 0.5 cm. The first line is drawn just within the edge of the screen. When ready, the strip is inserted into the base of the screen.

Received for publication, May 5, 1942.

By raising and lowering the screen, the widest diameter of the heart can be projected to this base line, and the measurement noted at once, giving the transverse diameter of the heart.

The patient must always stand touching his back to the fluoroscope, while the screen rests against the chest wall, and the head faces directly forward. The reading is taken at the end of inspiration. Under these conditions the measurements will be consistent and accurate. The figure obtained remains constant for the same patient under the same conditions. Repeated observations have borne this out. Little practice is required for rapid acquisition of the technique.

TABLE I

C. C.	51	M	146	64	128	142	14

This method of measurement has its greatest advantages when repeated studies of cardiac size are desired, especially at no material expense. Where changes in cardiac size occur, definite alteration in diameter can be determined at once. In the reversibly enlarged hearts of beriberi, myxedema, arteriovenous fistula, and cardiac dilatation, repeated measurements become invaluable and are easily determined by this method. Progressive enlargement or retrogression in the size of the heart can be observed easily, and recorded. Studies by Garland and McKenney[2] on the reversibly enlarged heart of thiamin deficiency revealed changes in the transverse diameter of the heart, as measured on 6 foot films, averaging a 2.7 cm. decrease in diameter in an average of fifteen days. The extremes varied from 1.0 to 4.5 cm. decrease in diameter of the heart, following the administration of thiamin. Such changes can be easily determined by the method herein described, without the use of film. Numerical records thus obviate somewhat repeated orthodiagrams and teleoradiograms.

Because of the closeness of the chest to the tube, the rays which strike the thoracic cage borders are too divergent for even approximate determinations of thoracic diameters which might conform to any tables. For the same reason

the larger the heart the more does its measure deviate from predicted figures. In this way, changes in size are more exaggerated than is actual, and therefore, more easily determined. The most accurate results are obtained in the normal heart size.

Ungerleider and Clark[3] in 1939 prepared tables of the transverse diameters of the heart, with which these measurements of the normal heart conform. The greatest deviation in the clinically normal heart was 9 mm. The least was 0 mm. Where clinical heart disease with enlargement existed, the figures roamed far from the predicted table.

In Table I are presented 15 patients with normal hearts, and five patients with hypertrophied hearts associated with hypertension. The comparative results by this method are easily seen.

SUMMARY

A simple method of immediate approximate measurement of the transverse diameter of the heart is described, obviating to a certain extent the use of orthodiagrams and teleoroentgenograms. Repeated studies in the same patient give excellent comparative results, and changes in the size of the heart are easily observed and recorded. Film is conserved, and time and expense are reduced to a minimum.

APPARATUS AND TECHNIQUE FOR MEASUREMENT OF VIBRATORY THRESHOLD AND OF VIBRATORY "ADAPTATION" CURVE*

CHARLES D. ARING, M.D., CINCINNATI, OHIO, AND W. O. FROHRING, B.S., CHAGRIN FALLS, OHIO

IN THE clinical study of neurologic disorders attempts have been made to determine the appreciation of vibration. Little is known concerning the physiologic factors underlying this phenomenon other than the fact that the integrity of certain neural pathways is essential.

In order to elucidate the influence of various physiologic factors, such as circulation, respiration, emotion, and such physical factors as temperature and pressure on the appreciation of vibration, it was necessary to consider quantitative procedures. Numerous attempts at quantitative measurement had been made with but little headway until 1929, when an instrument was constructed for Tilney by Henney.[1] Subsequently, Laidlaw and Hamilton[2] improved this instrument (pallesthesiometer) and employed it to study the vibratory thresholds of various body surfaces. In spite of improvements, however, certain shortcomings still existed in the apparatus. It was our aim to devise an instrument which would retain the simplicity of the one constructed by Laidlaw and Hamilton, and at the same time eliminate certain variables which seemed inherent in their apparatus.

DESCRIPTION OF APPARATUS

The apparatus which was devised for these studies is illustrated in Fig. 1, the wiring diagram in Fig. 2. A Raytheon automatic voltage regulator was employed to reduce the voltage variation to plus or minus 0.5 per cent. The vibrating applicator has a standard resistance of 90 ohms and differs from the instruments employed by other investigators in that it vibrates horizontally, rather than vertically, to the surface of the area. Since an increase of pressure would tend to dampen the amplitude of vibrations applied vertically to the skin area, horizontal vibration was chosen, for it is less likely to be affected by pressure variation.

Results of preliminary tests on several subjects indicated that a maximum voltage of 50 would cover the most practical range with a 5,000 ohm potentiometer if the latter were "even" wound rather than "taper" wound. A dial divided into 100 divisions gives a more nearly logarithmic function of the amplitude than does a dial calibrated in arithmetic units. The arbitrary use of the dial reading for recording determinations seems to be entirely practical for comparing results. Because of possibility of error in calibration

methods, no attempt was made to calibrate the dial readings in terms of "units of energy" or "amplitude." In the preliminary studies, when the pallesthesiometer had an input of 110, the dial reading at zero (with the voltage across the vibrator) was 4½ volts; at a maximum dial reading of 93, 49 volts. In case the automatic voltage regulator is not used, a variable resistance must replace the dropping resistor in the vibrator circuit and a voltmeter must be placed across the leads to the vibrator. When only direct current is available, an electronic 60-cycle convertor may be inserted ahead of the instrument.

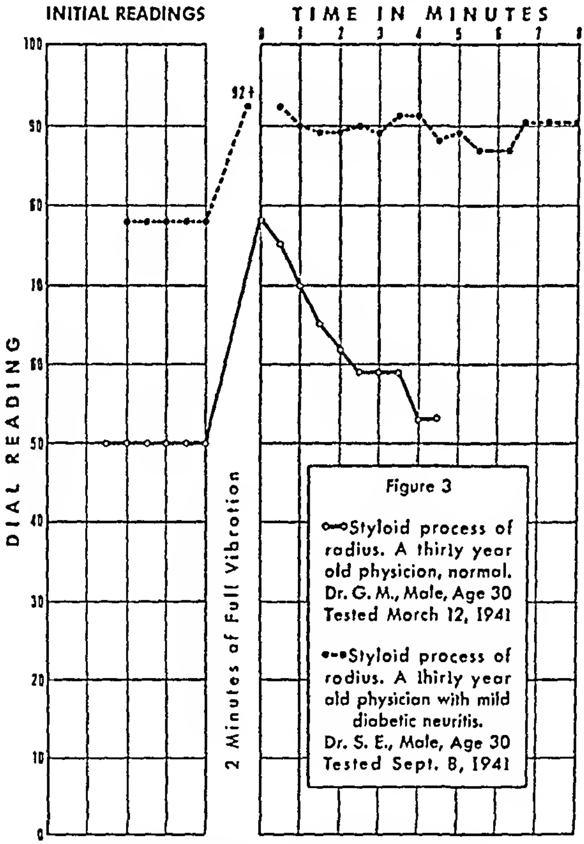

Fig. 3.—Vibratory "adaptation" curves.

METHOD

A modicum of attention is required on the part of the subject. After the procedure is explained, the subject may recline in the dorsal or ventral position. The vibrator is then applied to an area remote from that to be tested, so that the stimulus might be recognized before the test is begun. The applicator is held at right angles to the point tested, the weight of the entire applicator at that position representing roughly the pressure exerted on the skin. The initial threshold is then determined. With the dial set at zero and the vibrator applied to the test area, the dial is turned up slowly until the stimulus is perceptible. This process is repeated several times, allowing rest periods of thirty seconds to one minute between stimulations. It would be

logical to assume that threshold readings could be verified by starting with a stimulus heavier than the threshold, turning the dial toward zero, and recording the point at which the subject no longer perceives vibration. However, such a procedure results in an "adaptation" to the stimulus, particularly if the latter is heavy and is applied for more than an instant. Hence, it cannot be used to determine the threshold value.

The rate at which vibratory thresholds are approached has no effect on the final reading; that is to say, a variation in the speed at which readings are taken will not influence the subject's response. If he is reporting inaccurately, widely divergent readings are observed, indicating that the subject made his report when he thought the stimulus should have been evident rather than when it was actually felt.

The phenomenon of "adaptation" proved to be useful as a more delicate evaluation of vibratory appreciation than that educed by threshold determination alone. If, having determined the threshold of a surface over a given period of time, a heavy vibration was applied, the vibratory threshold was raised. When the "adapting" vibration was discontinued, it was found that the threshold returned to the original level in a period of a few minutes.

RESULTS

Vibratory thresholds were determined in normal persons. It was observed that readings in comparable test areas may vary widely from person to person. It is well known that the threshold varies from area to area on the body surface. Thus, Laidlaw and Hamilton[2] found that the vibratory threshold was lowest in the finger tips and highest at the sacrum.

Somewhat more constant was the adaptation to an intense stimulation. In the majority of subjects, return to the control threshold after a period of intense vibratory stimulation was observed in several minutes (Fig. 3). A much longer interval of return was observed in patients suffering from a variety of neurologic diseases (degeneration of the posterior columns of the spinal cord, subacute combined degeneration of the spinal cord, and peripheral neuritis) (Fig. 3). The influence of various physiologic and physical factors on vibratory appreciation in normal and abnormal states will be described in subsequent reports.

SUMMARY

An instrument for the quantitative measurement of the threshold of vibratory appreciation is described.

A SIMPLE KIDNEY PLETHYSMOGRAPH*

FREDERICK E. EMERY, PH.D., BUFFALO, N. Y.

THE kidney can easily be approached, and by means of a little dissection can be freed from the abdominal wall and placed in a plethysmograph. Usually some difficulty is experienced in obtaining records of kidney volume because the plethysmographs adapted for the kidney have some disadvantages. *First*, they are difficult to make airtight; *second*, the vena cava or kidney vessels are often compressed, resulting in passive congestion; *third*, the instrument is frequently too large to be inclosed in the abdomen and, therefore, the temperature of the kidney may be below normal; and *fourth*, the composition of the plethysmograph prevents visual inspection of the inclosed tissue. With these points in mind a simple plethysmograph has been devised which eliminates all these objections.

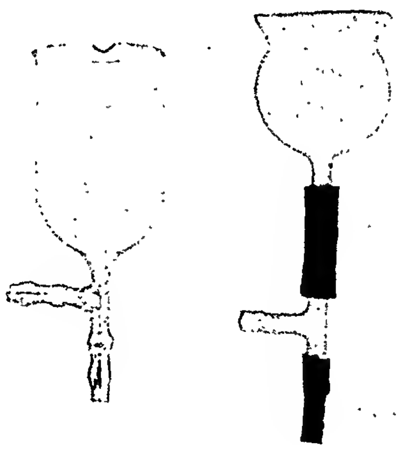

Fig. 1.

PLETHYSMOGRAPH

The plethysmograph is a cylinderical cup-shaped glass container. The bottom is entirely open and the top is closed, except for the opening of the outlet tube. The one shown on the right in Fig. 1 was made for large cats and is 40 mm. in diameter and 50 mm. high (this height is somewhat greater than actually needed). The two outlet tubes are clearly seen at the top of the picture, while at the bottom the notch intended for the passage of blood vessels is evident. This plethysmograph was made by a local glass blower. A workable, and in our experience equally satisfactory, apparatus for small cats can be made from a large thistle tube connected with a glass T-tube by means of rubber tubing (Fig. 1).

*From the Department of Physiology, University of Buffalo.

TECHNIQUE

The usual procedure of opening the abdomen and dissecting the kidney free from attachments is employed. The plethysmograph is prepared for use by placing a short rubber tube on the straight outlet arm. Through this tube, and extending through the bottom opening of the plethysmograph, a suture thread is passed. A small wire is used to pull the thread through the tube and plethysmograph. A suture needle is used to fix the lower end of this thread to the capsule of the kidney. The plethysmograph is now placed over the kidney, adjusted, and held in the desired position by means of a clamp from a base stand. The thread is pulled and the kidney is suspended in the glass chamber under as little tension as possible. A pinch clamp on the rubber

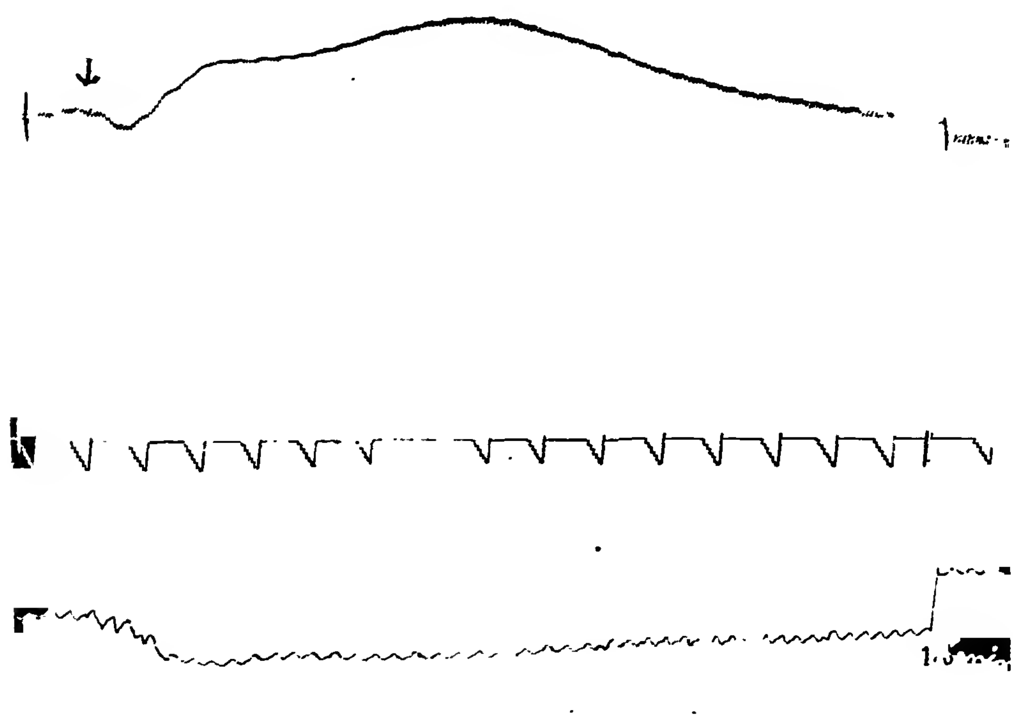

Fig. 2.—Blood pressure of a cat taken with a mercury manometer, upper tracing; base line and time in five seconds, middle tracing; and record of kidney volume, lower tracing. Note the return of the kidney volume to even less than normal during a rest period of one and one-half minutes. A single dose of 0.5 c.c. of a 1:50,000 solution of adrenalin given as indicated. Cat weight 2,000 Gm.

tubing holds the thread from slipping and closes the opening in the tubing. The kidney can be clearly seen and the plethysmograph can be adjusted so as to relieve all pressure on the vessels. A little warm mineral oil placed in the abdomen will make the plethysmograph airtight. Frequently no oil is required to make an airtight seal. If the intestines enter the plethysmograph, these may be blocked off with cotton rolled in vaseline, provided care is taken not to obstruct the veins of the kidney. The whole area is kept warm by closing the abdominal wall around and over most of the plethysmograph. The side arm of the plethysmograph is attached in the usual way to the recording tambour.

Records taken of kidney volume usually clearly show respirations and heartbeats, as well as changes in volume due to vasomotor activity. Fig. 2 shows the effect of adrenalin injected intravenously in an anesthetized cat. The expected rise of blood pressure occurs and constriction of the kidney, as indicated by the fall in the plethysmographic record, is evident.

AN ACCURATE CONSTANT TEMPERATURE WATER BATH CONSTRUCTED AT VERY LOW COST*

Benjamin C. Riggs, M.D., Philadelphia, Pa.

THE need for a small, accurate, constant temperature water bath of low cost led to the development of the design described. The accuracy was to be within 0.1° C. and the capacity 2 liters. The final cost came to less than four dollars. The uses for such a bath in the office or hospital laboratory are readily apparent and include blood amylase and lipase, trypsin, urea, amino acids, calcium, gastric enymes, inactivation of serum, and vaccine preparation.

Theory.—Essentially, the apparatus consists of an electrically powered immersion heater, controlled by a simple thermoregulator, installed in a small water bath of suitable shape to insure thorough mixing by convection.

The relation between vapor tension and temperature has long been known and practically used. In the design described, a mercury column, driven upward by the rising vapor tension of a suitable fluid subjected to rising temperature, is coupled at an adjustable point to a small mercury manometer. One arm of this manometer serves as the moving element of a single pole switch, making and breaking the power circuit of the heater. Undesirable arcing in the switch is eliminated by a low capacity condenser connected across the switch circuit.

The heating element also uses a well-known principle. The resistance to alternating current of a low concentration of electrolytes in water is used to produce high temperatures within a small space. In this design, two heavy gauge, parallel wires are immersed in the tap water of the bath and connected to either side of the 110 volt A.C. house circuit through a thermoregulator. When this is in closed position, the water between the exposed wires is kept at boiling temperature. Power consumption is regulated to suit the size and temperature of the bath by a sliding insulator covering one of the wires.

To eliminate the conventional mechanical stirrer, the heater is placed centrally in an approximately hemispherical bath, with the result that convection currents eliminate any temperature variations outside the sensitivity limits of the thermoregulator. (The presence in the bath of test tubes, flasks, etc., presents no measurable interference if the spacing between each is at least 2 cm.)

Construction.—1. Heater. (Cost of materials, approximately 50 cents.)

For temperatures up to 45° C., a single pair of parallel, 18 gauge wires, of 6 cm. exposed length, 2 mm. apart, will deliver sufficient heat to maintain

*From the Laboratory of the Germantown Hospital, Philadelphia.

Received for publication, May 19, 1942.

the temperature in 2 liters of water; the circuit will be closed not more than 50 per cent of the time. For higher temperatures or larger baths a double unit is more satisfactory: two pairs of wires are used, one pair operating continuously; the other, connected in parallel, running intermittently through the thermoregulator circuit. The construction is essentially the same in either case.

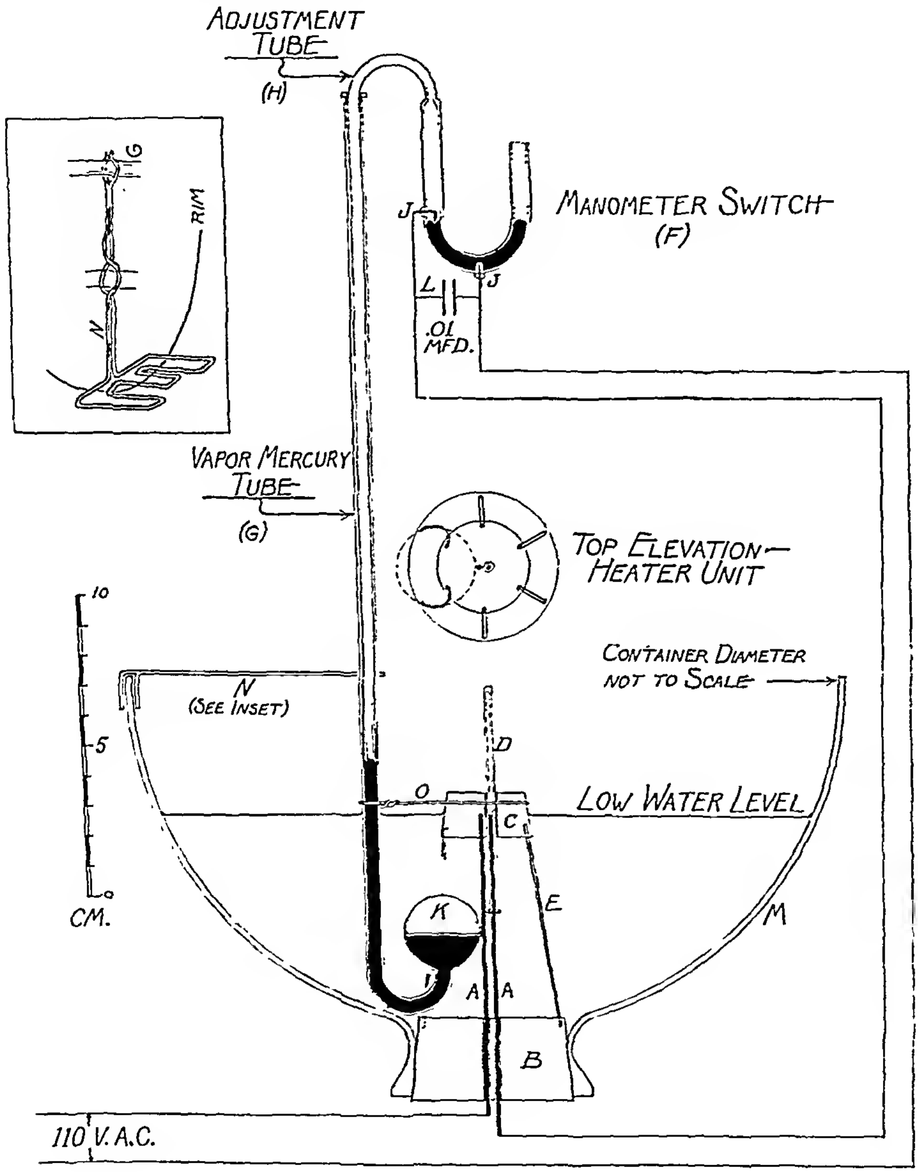

Fig. 1.

Although the apparatus now in use was built with copper heating wires, it is probable that some other metal, such as stainless steel or silver, would be less liable to the formation of objectionable salt crusts.

The heating wires (*A*) are passed through the rubber stopper (*B*) forming the base (of a size to fit tightly the neck of the container), and are secured by insertion into the rubber stopper (*C*) forming the top of the heater. A single

hole is bored in (*C*), at the insertion of one wire of each pair, to fit the glass insulating tubes, shown (*D*) in the single unit. These are lubricated with stop-cock grease; their position regulates the amount of exposed wire surface, and hence, the power consumption. A guard is built around the heating wires of painted iron wires (*E*), six in number, spaced evenly about the periphery, the ends inserted in the top and bottom stoppers. Two of these will be spread slightly to accommodate the vapor bulb (*K*) after it is constructed.

2. Thermoregulator. (Cost of materials approximately $2.50.)

Two sizes of soda lime glass tubing are used and enough "881" glass to form two beads about 2 mm. in diameter. The switch (*F*) and vapor mercury tube (*G*) have an *inside* diameter of 5 mm., and the adjusting tube (*H*) has an *outside* diameter of 4 mm. The "881" glass is used as a sealing medium around the platinum switch electrodes (*J*), because its coefficient of expansion is almost exactly that of platinum, thereby avoiding cracks. The vapor bulb (*K*) is blown to approximately 2.5 cm. diameter from the sealed end of the vapor mercury tube (*G*) *before* bending. Properly placed holes, 1 mm. in diameter, are blown in a *previously* bent section of the same sized tubing to form the manometer switch (*F*). One centimeter lengths of 20 gauge platinum wire (*J*) are sealed into these holes in beads of "881" glass. The adjusting tube (*H*) is sealed to the manometer *after* bending, and is fitted with a snug rubber washer cut from tubing to enable it to be set at any desired height within the vapor mercury tube (*G*). The 0.01 microfarad tubular condenser (*L*) is mounted between the outside ends of the electrodes to facilitate wiring and give support to the electrodes and seals. The mercury in the switch should just make thorough contact with the upper electrode, with both sides unobstructed, and the adjusting tube vertical.

The vaporizing fluid in the vapor bulb is best chosen by trial and error for the temperature range contemplated. Satisfactory results have been obtained with mixtures of ethyl ether and absolute ethyl alcohol, for temperatures from 35° C. to 45° C., and with petroleum ether from 40° C. to 60° C. The amount of fluid, size of air bubble, and amount of mercury are also best found by experiment. (The author used mercury 10 c.c. and fluid 0.5 c.c.)

The wiring should be evident from the diagram. A second heating unit is simply wired directly across the power lines. It has been found convenient to wire the manometer switch to a plug, fitting into a socket at the base of the heater, to facilitate removal for cleaning the bath.

3. Container (*M*). (Cost of materials, approximately $1.00.)

The most satisfactory container was found to be an inverted glass lamp shade of hemispherical shape, the neck receiving a No. 11 rubber stopper, the rim about 30 cm. in diameter. This pattern is easily obtainable for about $1.00 and has been perfectly suited.

The thermoregulator is so placed that the vapor bulb passes between two of the guard wires, slightly spread to receive it, and rests in contact with the heating element. (This should be the intermittent heating element if a double unit is used.) The vapor mercury tube is held vertically by a simple clamp (*N*) bent from iron wire, slipping onto the rim of the container. An auxiliary clamp

(*O*) is bent in the form of a double-ended hook to steady the bulb against the heating element. Clamp (*N*) is also bent to receive a standard, mercury immersion thermometer.

Operation.—The apparatus is designed for use on the standard, 110 volt A.C. circuit. Continuous operation requires a daily check on the water level and flushing out of the bath weekly. No other attention has been found necessary. When beginning use, the bath should be filled with water at approximately the desired temperature, and the adjusting tube raised so that the switch just makes contact. Final adjustment is postponed until the thermoregulator and bath have reached equilibrium, or about one-half hour after filling. The maximum over-all variations in temperature have not been observed to exceed 0.2° C.

SUMMARY

A new design is described for an extremely inexpensive, small, easily constructed, constant temperature water bath, for use in the hospital or office laboratory. The theory, construction, and operation are given in detail.

LEVINSON TEST FOR TUBERCULOUS MENINGITIS*

Presentation of 110 Cases and a Discussion of the Principle and Technique of the Test

Daniel Burman, A.M., M.D., and Roslyn Weintraub, B.A.
New York, N. Y.

INTRODUCTION

The Levinson test for tuberculous meningitis is a very accurate diagnostic procedure. A study of the literature and a personal survey of several hospitals and many physicians revealed that this test is little known and used still less. As a result, we feel that a presentation of the results of this test on 110 cases, a review of the results of previous investigations, and a discussion of the principle and technique will be of value and may serve to increase the use of this valuable adjunct in the diagnosis of meningitis.

HISTORY

In 1917 Tashiro and Levinson[1] published a report on the alkaloidal and metallic precipitation of cerebrospinal fluid in the diagnosis of meningitis. It was not until 1919 that this test again appeared in the literature. At that time Levinson[2] included it in his book on spinal fluid without discussing its principle. The first clinical report that we could find on this subject was the paper published by Gleisch[3] in 1932. In this paper he discusses the test and reports that in his cases the results were uniformly good. The same author[4] again published a clinical report in 1938 in which he states that 51 cases (Tables I, II,

*From the Otolaryngology and Pathology Departments of Harlem Hospital, New York, N. Y.

Received for publication, May 22, 1942.

III) were examined and tested by this method with very good results. The report showed 38 cases with a positive Levinson test and 13 cases with a negative result. Of the 38 cases, 23 revealed tuberculosis organisms; 6 showed tuberculosis at autopsy; one tuberculous patient had tuberculosis organisms in the spinal fluid; and 8 did not have tuberculosis. However, of these 8, one had an intracranial hemorrhage with multiple lacerations; 2 had cerebral hemorrhage with hypertensive cardiovascular disease; one had encephalitis lethargica; 3 were epileptics; and one had staphylococcus meningitis. All the 8 nontuberculous meningitis cases were positive, since there was either blood or serum present in the spinal fluid. Of the 13 negative tests all were nontuberculous, 10 had a meningococcic meningitis, and 3 had poliomyelitis.

In 1939 Gleisch and R. Weintraub[5] published a study of the comparative value of the Levinson and tryptophan tests in the diagnosis of tuberculous meningitis. They pointed out that the tryptophan test was markedly inferior to the Levinson test. Their results showed (Table IV) that in 18 cases of positive tuberculosis all had positive Levinson tests, but only 16 had a positive tryptophan A, 12 a positive tryptophan B, and 2 were negative in both tryptophan A and B tests. Furthermore, in 8 cases of nontuberculous meningitis with clear fluid (Table V) all had negative Levinson tests, but 8 had a positive tryptophan A and 3 had a positive tryptophan B. They also showed that in 7 cases of bloody spinal fluid and 9 cases of purulent meningitis (Table VI) all had positive Levinson and tryptophan tests; and that in 14 cases without meningitis all had negative tryptophan and Levinson tests.

In 1940 S. Weintraub[6] published a paper on the various diagnostic procedures for tuberculous meningitis. He was favorably impressed with the results of the Levinson test.

TECHNIQUE

Into each of two small test tubes of uniform width, about 0.3 cm. in diameter, place 1 c.c. of spinal fluid. Add to one of the tubes 1 c.c. of 3 per cent sulfosalicylic acid and to the other 1 c.c. of 1 per cent mercuric chloride. Stopper the tubes and allow them to stand for from twenty-four to forty-eight hours at room temperature and then measure the height of the sediments. (The very small flat-bottomed serum vials are very useful tubes to use for this test.) Normally, both are very small; in suppurative meningitis the sulfosalicylic precipitate is very heavy and the mercuric chloride precipitate is very small. In

tuberculous meningitis the opposite takes place, the sulfosalicylic acid precipitate being small and the mercuric chloride precipitate being large. In order to read a positive Levinson test the foregoing conditions must be fulfilled and the mercuric chloride precipitate must be from two to three times as great as the sulfosalicylic precipitate; that is, when measuring the height of the precipitate in the two tubes, diameters of which are the same, the height of the mercuric chloride precipitate must be two to three times as large as that of the sulfosalicylic acid. It is to be remembered that this test is only to be performed on clear spinal fluid.

TABLE IV

COMPARATIVE VALUE OF THE LEVINSON AND TRYPTOPHAN TESTS IN 18 CASES OF PROVED TUBERCULOUS MENINGITIS

PRINCIPLE

The spinal fluid of tuberculous meningitis, like normal spinal fluid, has a pH of approximately 7.4 immediately after withdrawal, but ascends to 8.1 or higher on standing for from twenty-four to forty-eight hours. Spinal fluid from epidemic meningitis has a pH 7.2 to 7.5 but goes up only slightly on standing from twenty-four to forty-eight hours. The more turbid the fluid the longer it retains its acidity. An explanation that has been offered for this phenomenon is as follows: Normal spinal fluid loses H ions on standing. However, if it is tightly corked it does not change its pH. Thus, this phenomenon may be due to the loss of carbon dioxide. Tuberculous meningitic spinal fluid reacts just as the normal spinal fluid, only more rapidly. Epidemic meningitic spinal fluid changes its pH very little and becomes more acid on being corked. This may be due to lactic acid formation.

Bacteriology is helpful in making a diagnosis when the results are positive. However, it is not of much aid when negative results are obtained. Globulin is increased in all meningeal inflammations, but the amount of increase does not help to determine the disease because the ranges overlap each other.

The pH of spinal fluid changes on standing and varies between epidemic and tuberculous meningitis, as discussed above. Levinson stated in 1917: "If the difference in the reaction of the different fluids is great enough, we should

be able to distinguish their protein in a variety of ways, even if their protein concentration might be the same. The electrical charge of a protein depends on the reaction of the medium. In acid solution proteins become electropositive and in alkaline solution electro-negative. Thus one of the ways of precipitating protein is to let it combine with some radical to form an insoluble salt. From the standpoint of the electrical charge of the protein, such a protein salt is necessarily either a positive protein radical forming a protein salt with the negatively charged ions (alkaline precipitates) such as tungstic acid, picric acid, etc., or negatively charged protein combining with a positively charged metal (metallic precipitates) such as copper, silver, mercury, zinc, and lead. If these protein salts are sufficiently insoluble, the precipitate will come down."

Diagnosed by finding the organism in the spinal fluid or on autopsy	41
Diagnosed by clinical, x-ray, and other laboratory tests	27
Deceased	68

Cataphoresis experiments proved that the protein in epidemic meningitis moves toward the cathode, showing the presence of positively charged protein ions, whereas in tuberculous meningitis the protein ions went to the anode, proving a greater number of negatively charged protein ions in this condition. In nonmeningitic fluids there is very little precipitation in cataphoresis. Thus the pH variation is enough to produce electrical charges in the protein. Therefore, it should be possible to choose proper precipitants to distinguish the various forms of meningitis; that is, there should be more precipitate with a metallic precipitant than with an alkaloid precipitant in tuberculous meningitis, and the reverse in epidemic meningitis. Experimental work subsequently proved this to be true.

Normal fluid is only slightly turbid when sulfosalicylic acid is added and remains clear with mercuric chloride. This condition obtains only immediately after the addition of these reagents. However, on standing both form precipitates. In tuberculous meningitis the addition of sulfosalicylic acid causes the fluid to become turbid immediately whereas with the addition of mercuric chloride the fluid remains clear. In twenty-four hours sediments are found in both tubes, but the precipitate due to the mercury is two to three times as much as that due to the sulfosalicylic acid. In epidemic meningitis the sulfosalicylic acid precipitates the protein quickly and the mercuric chloride precipitates the protein slowly. In this case twenty-four hours after the addition of the pre-

cipitants the sulfosalicylic acid sediment is two to three times as great as that of the mercuric chloride. It cannot be overemphasized that the principal feature in this test is the ratio and not the total amount of precipitate which is found, and this is directly dependent upon the pH of the protein.

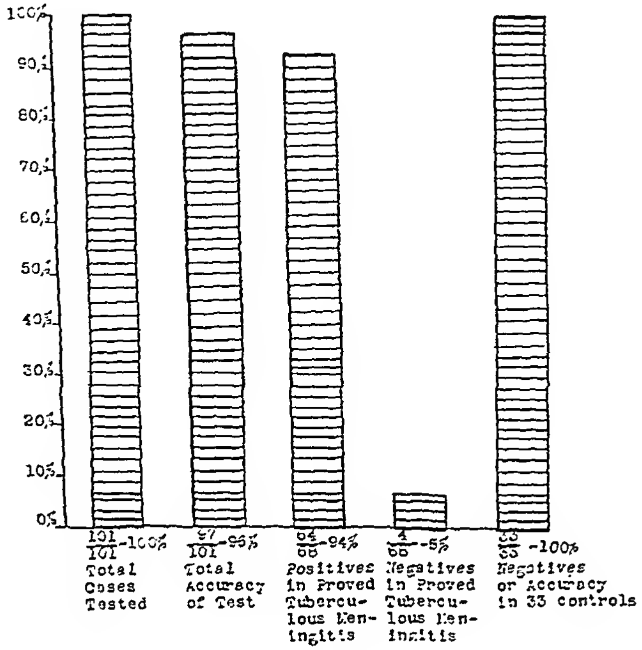

Fig. 1.

CASE STUDIES

The spinal fluids of 110 cases were examined. Nine of these had to be discarded for the following reasons: Six had red blood cells and three had insufficient fluid for a Levinson test after the other tests had been performed. As a result we have only 101 cases on which tabulations can be based. There were 68 cases of tuberculous meningitis and 33 controls. These 33 cases were diagnosed as meningismus, nontuberculous meningitis, or cases in which no meningeal signs were present. Sixty-four of the 68 cases were positive while 2 were negative and 2 gave equivocal results when tested by the Levinson method; that is, 2 could have been read either way—positive or negative. We are considering these as negative results. Thus we have 4 negative results. Of the 33 controls all gave negative results in this test.

Forty-one of the 68 cases, or 60.3 per cent, were proved to be tuberculous meningitis by one or more of the following methods: finding the organism in the spinal fluid or autopsy. The other 27, or 29.7 per cent, were diagnosed as tuberculous meningitis on the basis of clinical, x-ray, and other laboratory findings plus the fact that they all died. Thus 64/68, or 94 per cent, gave positive Levinson tests, and 4/68, or 6 per cent, gave negative Levinson tests. Furthermore, all the controls, that is, 33/33, or 100 per cent, gave negative Levinson tests; or, to express it in another way, 97/101, or 96 per cent, gave accurate results by the Levinson method.

If we now combine our results with those reported above, taken from the literature, there is a total of 217 cases. Of these, 116 were proved to be tubercu-

lous meningitis and gave 112 positive results and only 4 negatives. One hundred and three were nontuberculous and gave the following results:

Positive Levinson tests 30

All had either red blood cells or pus in the spinal fluid

Negative Levinson tests 70

These were made up of normals and cases of poliomyelitis, meningismus, nontuberculous meningitis, and 2 equivocal cases.

Quantity Insufficient for a Levinson test 3

After all the routine tests were performed, there was not sufficient spinal fluid left for the performance of the Levinson test.

COMMENT

We have presented 217 cases which were studied for the determination of the accuracy of the Levinson test. Of these, 110 were our own and 107 were from the literature. Our results revealed that this test is 94 per cent accurate, whereas the total of our cases plus those of the other investigators (who found 100 per cent accurate results) brings the percentage of accuracy up to 97. As this compares favorably with any other diagnostic laboratory procedure, and as the number of cases studied is not too small, we feel that this simple laboratory test should be used more often in the diagnosis of meningitis.

It should be evident from this paper that the test is of value only in cases of meningitis where the spinal fluid is clear and where no serum has been administered, since pus, red blood cells, and serum render the spinal fluid more alkaline and result in a false positive.

SUMMARY

1. The history and a summary of the literature on the Levinson test are presented.

2. A description of the technique and the principle on which the test is based are given.

3. A total of 110 new cases and 107 cases in the literature on which the Levinson test was performed, together with a breakdown of the results to determine the accuracy of the test, is presented.

4. Tables showing the test from 94 to 97 per cent accurate in diagnosing tuberculous meningitis are included.

5. A bibliography of all the available literature on this subject is presented.

CHEMICAL

THE DETERMINATION OF TOTAL CHOLESTEROL AND CHOLESTEROL ESTERS IN BLOOD*

S. L. Leiboff, New York, N. Y.

METHODS for the quantitative determination of cholesterol esters in blood have been devised by Bloor and Knudsen,[1] Sperry,[2] Kelsey,[3] and others. In all these methods the free cholesterol is separated from the esters by precipitation with digitonin. For the quantitative estimation of both free and combined cholesterol, practically all methods utilize the Liebermann-Burchard color reaction.

Various procedures are used for extracting the cholesterol from blood. Bloor[4] extracts it from wet blood with a mixture of alcohol and ether. Myers and Wardell[5] dry blood with plaster of Paris and extract with chloroform. I[6] dry the blood on fat-free filter paper and extracts with chloroform.

Because of the difficulties inherent in these methods, requiring a great deal of time and painstaking manipulation, a study was undertaken to determine the conditions best suited to produce the quickest and most accurate results. This study culminated in the development of an extremely simple and accurate method for the determination of total cholesterol and cholesterol ester content in blood.

PRINCIPLE OF METHOD

Oxalated blood is mixed well with anhydrous sodium sulfate and extracted with chloroform for twenty minutes in a graduated test tube attached to an air-cooled condenser. The chloroform extract is filtered and two aliquot portions are removed. One portion is treated directly with acetic anhydride and sulfuric acid for the total cholesterol content. The second portion is used for the determination of esters as follows: The chloroform is removed by evaporation and substituted by petroleum ether from which the free cholesterol is removed with digitonin. The petroleum ether is evaporated, the esters are taken up in chloroform, and the color is developed with acetic anhydride and sulfuric acid. Both fractions are determined colorimetrically against a standard containing a known amount of cholesterol.

Preparation of Reagents.—It is important that the reagents used in the test be of the highest purity; this applies particularly to the chloroform and acetic anhydride. The following methods for the purification of these reagents have proved very satisfactory.

Purification of Chloroform.—Into a 2,000 c.c. separatory funnel introduce 1,000 c.c. of chloroform and 100 c.c. of concentrated sulfuric acid. Shake at intervals during twenty-four hours. Remove the sulfuric acid and wash the

*From the Laboratory of Lebanon Hospital, New York.
Received for publication, March 15, 1941.

chloroform with a slow stream of running water passing through a glass tube reaching to the bottom of the separatory funnel until neutral to litmus. Transfer the chloroform to a distilling flask and add 50 Gm. of anhydrous calcium chloride. Shake at intervals during twenty-four hours and distil, discarding the first and last 50 c.c. of chloroform. Transfer the distilled chloroform to an amber bottle and add 0.7 c.c. of absolute alcohol per 100 c.c. of chloroform and a few grams of anhydrous calcium chloride. The alcohol acts as a preservative. Keep the bottle tightly stoppered.

Purification of Acetic Anhydride.—Heat 500 c.c. of acetic anhydride with 50 Gm. of calcium oxide in a distilling flask under a reflux condenser for three hours. Allow to stand overnight and distil slowly. Keep in brown bottle with tightly fitting glass stopper.

Preparation of Digitonin Reagent.—In a small flask place 1 Gm. of digitonin, 10 c.c. of methyl alcohol, and 10 c.c. of distilled water. Place the flask in a beaker containing water heated to about 60° C. and rotate the flask until the digitonin is completely dissolved.

On standing the digitonin separates out of solution. It is, therefore, necessary to redissolve it by placing in hot water before use. It redissolves very readily.

Preparation of Cholesterol Standard.—Prepare a stock solution by dissolving 0.160 Gm. of pure cholesterol in 100 c.c. of chloroform. A working standard is prepared by diluting 5 c.c. of the stock standard with 95 c.c. of chloroform. Five cubic centimeters of the working standard contain 0.4 mg. of cholesterol. The standards are kept in the refrigerator in amber bottles.

Extraction Apparatus (Fig. 1).—The apparatus consists of a graduated glass tube 20 by 150 mm. The graduation marks start at zero about 40 mm. from the bottom of the tube and continue upward to a mark of 60. These graduation marks do not represent specific volumes but are used to indicate the chloroform level in the tube. The inside mouth of the tube is ground to fit a coiled glass air-cooled condenser. The whole length of the condenser is 260 mm. and the coiled portion consisting of six coils is 100 mm. long and 10 mm. wide. This condenser is a modification of the one suggested by Breh.[7]

The glass rod is 220 mm. long and 5 mm. in diameter.

PROCEDURE

Determination of Total Cholesterol.—When a determination of the total cholesterol only is required, the following procedure is to be followed:

Place 0.5 c.c. of oxalated blood into the extraction tube and add approximately 2 Gm. of anhydrous sodium sulfate and exactly 10 c.c. of chloroform. Mix with a glass rod to a homogeneous mixture by pressing and rubbing the rod against the walls of the tube. Hold up the extraction tube in a perfectly vertical position level with your eye, and without removing the rod, read the graduation mark at the meniscus of the chloroform. Attach the condenser to the tube without removing the rod, and heat gently over a microburner or an electric heater for ten minutes. Allow to cool for a few minutes, detach the condenser, and stir up the powder thoroughly with the rod. Attach the condenser and heat for ten more minutes to complete the extraction. Allow to cool to room temperature and add chloroform to the original graduation mark. Mix well with

the rod and filter through a very small piece of absorbent cotton packed somewhat tightly in the stem of a small glass funnel. Keep the funnel covered with a watch glass to prevent evaporation.

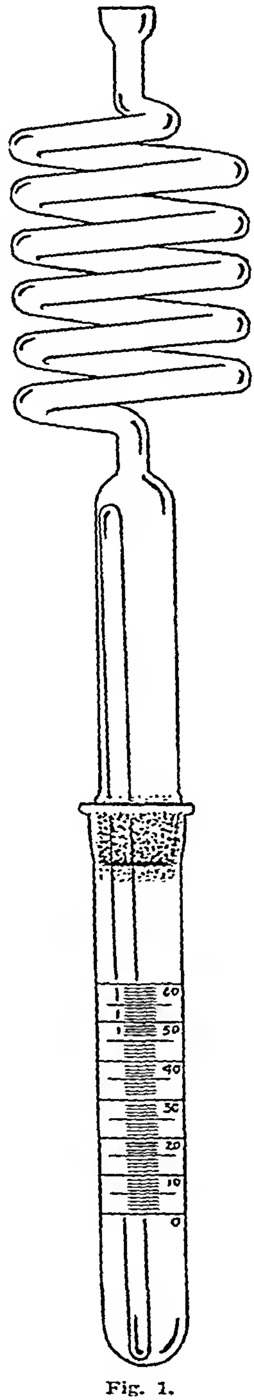

Fig. 1.

Transfer 5 c.c. of the chloroform extract to a test tube. In another test tube place 5 c.c. of the working standard (equal to 0.4 mg. cholesterol). Place the standard and the unknown in a beaker of water kept between 20° and 25° C.

Add to each tube 2 c.c. of acetic anhydride and 0.1 c.c. of concentrated sulfuric acid. Cover the tubes with clean dry corks, mix contents, and set aside in a dark place for twenty minutes. Compare colors in the colorimeter by setting the standard at 15 mm.

Calculation of Result.—

$$\frac{2400}{X} = \text{Milligram of cholesterol per 100 c.c. of blood.}$$

$$X = \text{Reading of the unknown.}$$

Determination of Total Cholesterol and Cholesterol Esters.—Place 1.5 c.c. of oxalated blood into the extraction tube and add approximately 6 Gm. of anhydrous sodium sulfate and exactly 15 c.c. of chloroform. Mix well with the rod and note the graduation mark at the meniscus of the chloroform. Extract for twenty minutes and filter through absorbent cotton, following all the steps already described under the determination of total cholesterol.

Transfer 2.5 c.c. of the chloroform to a test tube and add 2.5 c.c. of chloroform. Stopper with a clean cork and set aside for the determination of total cholesterol.

Transfer 7.5 c.c. of the chloroform extract into a test tube (20 × 150 mm.). This is for the determination of cholesterol esters. Place this tube in a water bath heated to about 70° C. until all the chloroform is driven off. Cool to room temperature and add 9 c.c. of petroleum ether (B. P. 30° to 60° C.) and 0.1 c.c. of digitonin solution previously heated to put in solution. Cork the tube and shake well; the cholesterin digitonide is precipitated immediately. Allow to stand for a few minutes and filter through a small piece of cotton tightly packed in the stem of a small funnel. In this case the cotton has to be packed very tightly so that no particles of digitonide can pass through.

Remove 6 c.c. of the petroleum ether filtrate into a similar large test tube and place in the water bath at about 60° C. until all the petroleum ether is completely evaporated. Allow the tube to cool to room temperature and add 5 c.c. of chloroform. This contains the cholesterol esters only.

Into a third tube place 5 c.c. of the cholesterol working standard.

Place the two unknowns and the standard in a beaker of cold water at a temperature between 20° and 25° C., and to each tube add 2 c.c. of acetic anhydride and 0.1 c.c. of concentrated sulfuric acid. Mix the contents and put the beaker in a dark place for twenty minutes and compare in the colorimeter with the standard set at 15 mm.

Calculation of Results.—

Total Cholesterol: 2,400 divided by reading of unknown
= milligrams per 100 c.c. of blood.

Cholesterol Esters: 1,200 divided by reading of unknown
= milligrams per 100 c.c. of blood.

Precautions.—The color developed by the action of acetic anhydride and sulfuric acid on cholesterol changes rapidly on removal from the water bath and on exposure to light. Since this change is at a different rate in the standard and in the blood extracts, it is important that the colorimetric matchings be made

as rapidly as possible after removal from the dark. It should not exceed three minutes. When a large number of cholesterol determinations are to be performed simultaneously, it is advisable to set up a number of standards and use a new standard every three minutes. Each standard is removed from the beaker simultaneously with the unknowns to be read. As this reaction is also seriously affected by water, it is important that all glassware used in this test be perfectly dry.

DISCUSSION

A number of experiments were conducted to check the accuracy of the method. The first step was to determine whether this method of extraction removes all the cholesterol from the blood. A series of extraction tubes were set up with 0.5 c.c. of blood in each. Cholesterol in increasing amounts were added to each successive tube. As is shown in Table I, the added cholesterol was completely recovered within experimental error.

TABLE I

RECOVERY OF ADDED CHOLESTEROL FROM BLOOD

TUBE	ORIGINAL CHOLESTEROL CONTENT IN 0.5 C.C. OF BLOOD (MG.)	ADDED CHOLESTEROL (MG.)	CHOLESTEROL IN EACH TUBE (MG.)	CALCULATED AMOUNT OF CHOLESTEROL IN 100 C.C. OF BLOOD (MG.)	AMOUNT OF CHOLESTEROL RECOVERED (MG.)
1	0.88	None	0.88	176	176
2	0.88	0.4	1.28	256	249
3	0.88	0.8	1.68	336	330
4	0.88	1.2	2.08	416	422
5	0.88	1.6	2.48	496	487
6	0.88	2.0	2.88	576	565

In another experiment cholesterol equivalent to 1,200 mg. per 100 c.c. of blood was dissolved in petroleum ether and precipitated with digitonin. The petroleum ether filtrate was evaporated and replaced by chloroform. Treatment with acetic anhydride and sulfuric acid failed to develop any trace of color, thus showing that the digitonin solution as used in this method completely precipitates free cholesterol.

RECOVERY OF CHOLESTEROL ESTERS

In this experiment cholesterol esters in increasing amounts were added to blood. The cholesterol esters were extracted from 100 c.c. of pooled blood mixed in a large flask with anhydrous sodium sulfate and extracted with chloroform.

TABLE II

RECOVERY OF ADDED CHOLESTEROL ESTERS FROM BLOOD

TUBE	ORIGINAL ESTER CONTENT IN 1.5 C.C. OF BLOOD (MG.)	ADDED ESTERS (MG.)	TOTAL ESTERS (MG.)	CALCULATED AMOUNT OF ESTERS PER 100 C.C. OF BLOOD (MG.)	CHOLESTEROL ESTERS RECOVERED PER 100 C.C. OF BLOOD (MG.)
1	0.93	None	0.93	62	61
2	0.93	0.5	1.43	95	94
3	0.93	1.0	1.93	129	131
4	0.93	3.0	3.93	262	256
5	0.93	5.0	5.93	395	388

The free cholesterol was completely removed with digitonin, and the cholesterol esters were dissolved in chloroform. Fifty-seven milligrams of cholesterol esters were obtained, as shown by a quantitative estimation. Varying amounts of these cholesterol esters added to samples of blood were completely recovered. This is shown in Table II.

More than four hundred determinations were performed by this method on blood coming to the laboratory for routine chemical examination. The average figure for total cholesterol in normal blood was about 180 mg., and the average ester content about 65 mg. per 100 c.c. of whole blood.

SUMMARY

A simple and accurate method for the determination of total cholesterol and cholesterol esters in blood is described. The blood is mixed with anhydrous sodium sulfate and extracted with chloroform. One aliquot portion of this extract is used for the determination of cholesterol esters after removing the free cholesterol with digitonin. The extracts are treated with acetic anhydride and sulfuric acid and compared colorimetrically with a standard cholesterol solution.

MICROCHEMICAL DETERMINATION OF YELLOW PHOSPHORUS*

LIEUT. SIDNEY KAYE,† U. S. ARMY

PHOSPHORUS is one of the more commonly known elements. It is, therefore, fitting and important that accurate, specific, and sensitive methods for its detection and determination should be available. The literature describes several satisfactory procedures based on gravimetric, volumetric, and colorimetric analyses. A new method for the confirmation and quantitative determination is herein described, using a spot test color reaction which is confined to a standard area the color intensity of which is proportional to the concentration of phosphorus present. This new method is not only specific and sensitive but also very simple. Its principle is based upon the formation of phosphine which in turn easily reduces a mercuric bromide test paper, yielding a canary yellow color.

Phosphorus may exist in several forms; the best known of these are yellow and red. Red phosphorus is considered by most authorities as nontoxic, whereas yellow phosphorus is very toxic and 0.1 Gm. has been recorded to be fatal. The method outlined here is applicable to yellow phosphorus only and is satisfactory, since our interest is primarily from a toxicologic viewpoint. Yellow phosphorus is used commonly in rat poison pastes and acute poisoning is usually accidental, but suicides and homicides have been recorded wherein phosphorus had been used.

Phosphorus may remain in the system for several days, but the greater the delay in obtaining the specimen, the less is the possibility of detecting it. The procedure of isolating it for analysis depends upon its volatility. Stomach contents are best suited for analysis.

A brief summary of the toxicology of phosphorus is included in this paper for completeness.

Symptoms.—Progressive pain and burning along the gastrointestinal tract, with belching, choking, vomiting, and diarrhea are present. The following additional symptoms are frequently noted: garlic odor on the breath, jaundice of the skin, bleeding from the nose and intestines, muscular paralysis and impairment of the special senses. Terminally, stupor, delirium, and coma occur. Death occurs usually within two to six days.

Treatment.—Wash the stomach with 1 per cent potassium permanganate and large amounts of suspended charcoal. If done quickly, this may be effective.

Post-Mortem Pathology.—There is corrosion of the mucous membrane of the gastrointestinal tract, with fatty degeneration and acute yellow atrophy of the

†First Lieutenant, Sanitary Corps.

Received for publication, May 16, 1942.

liver. The stomach contents, as a rule, have the odor of garlic, and if viewed in the dark, give off a greenish phosphorescent light.

Chemical Analysis.—The following qualitative tests have been used to identify phosphorus positively:

1. Odor: The garliclike odor may be recognized on opening the stomach.

2. Scherer's test: A portion of the finely divided material is placed in an Erlenmeyer flask and suspended in distilled water. Two strips of filter paper are suspended over the suspected sample, one impregnated with silver nitrate and the other with lead acetate. The contents are heated at about 50° C. on a water bath for approximately an hour. If the silver nitrate paper turns black, either phosphorus or hydrogen sulfide may be present. If both papers turn black, hydrogen sulfide is present and phosphorus may also be present. The fact that the silver nitrate paper turns black is not conclusive proof of the presence of phosphorus, since any volatile reducing agent, such as formaldehyde, may also give the same reaction. Therefore, this test is more important in indicating the absence of phosphorus rather than its presence.

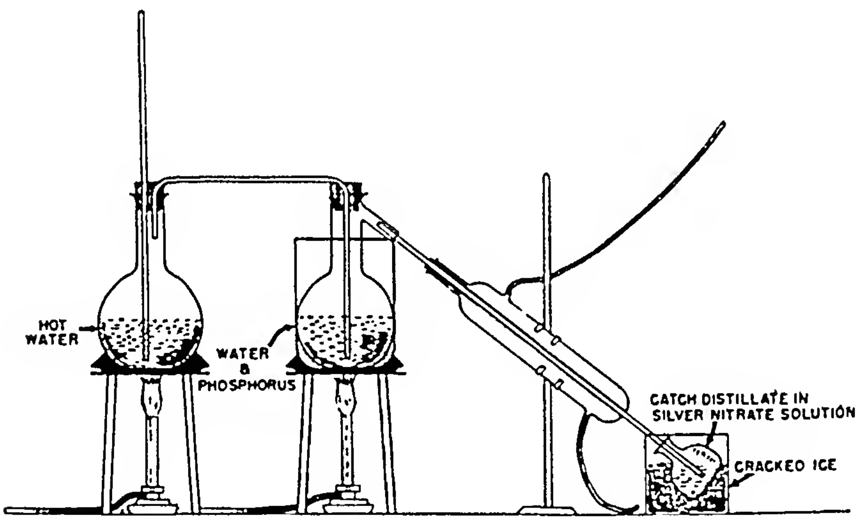

Fig. 1.

A NEW QUANTITATIVE TEST FOR PHOSPHORUS

A weighed aliquot of the sample is transferred to a steam distillation apparatus with about 100 ml. of water and an ice-cooled receiver is used to collect the distillate, as illustrated in Fig. 1. The light from the Bunsen burner is shielded by a sheet of asbestos to prevent any interference in the visual detection of the phosphorescence emitted. The distillation is performed in the dark, and the distillate is collected in a small volume of 0.5 N silver nitrate, which is cooled in a 125 ml. Erlenmeyer flask immersed in an ice bath. Greenish phosphorescence* may be seen as the phosphorus vapors reach the condenser. As little as 60 gamma† in 200 Gm. of material give a good phosphorescence. However, in the presence of alcohol, ether, benzene, turpentine, phenols, chloroform, essential oils, oxidizing agents, mercury, copper, and silver there may be a marked

*Mitscherlich's phosphorescence test.
†One gamma = 0.000001 Gm. or 0.001 mg.

diminution or complete absence of the phosphorescence. The distillation is continued until about 75 ml. are collected. As the first traces of phosphorus come over into the silver nitrate solution, a black precipitate of silver phosphide forms. After about 75 ml. have been collected, it will be noticed that on continued distillation no further precipitate forms. Silver phosphide is a heavy precipitate and settles rapidly. The supernatant liquid is siphoned off without disturbing the precipitate, leaving a small amount of liquid behind. The precipitate is then washed in the flask with several portions of distilled water to remove the last traces

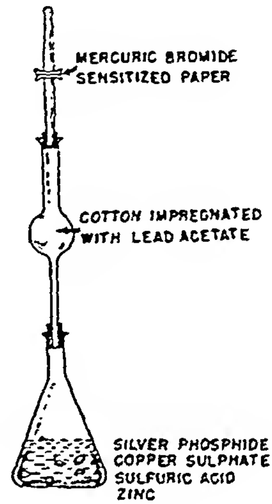

Fig. 2.

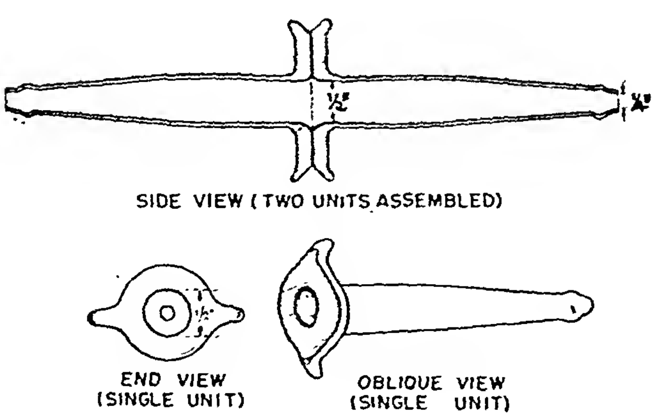

Fig. 3.

of any adhering silver nitrate. The supernatant fluid is again siphoned off. Two washings usually suffice. The washings are tested for silver ions by a chloride solution. If the precipitate is scant in the receiving vessel, make up volume to 50 ml. with water. If the precipitate is heavy, dilute to a larger known volume with water. Swirl the solution well so as to divide evenly the precipitate, withdraw a recorded small aliquot portion, and add it to a previously prepared modified Gutzeit apparatus (Fig. 2). This is essentially a 125 ml. Erlenmeyer flask containing some arsenic-free zinc, several drops of 5 per cent copper sulfate solution to

activate the process, and 25 to 40 ml. of 20 per cent sulfuric acid. The amount of sulfuric acid used should be sufficient to dissolve the precipitate in the aliquot added; excess does not interfere. The stopper in the flask supports a small calcium chloride drying tube into which is plugged some cotton impregnated with lead acetate. Above this tube is attached a set of flanges* between which is placed a disk of mercuric bromide† sensitized filter paper. On contact of the silver phosphide with the hydrogen generating solution, phosphine is liberated. The generating flask is kept warm on a water bath at about 50° C. Phosphine travels upward and is purified from hydrogen sulfide by passage through the lead acetate cotton. On reaching the flanges when it contacts the moistened mercuric bromide paper, a yellow color results which is directly proportional to the phosphine produced. Since the bores of the several flanges are uniform, comparisons can be made with phosphorus standards prepared in a similar manner. This color reaction is sensitive to less than 10 gamma of phosphorus. To be certain that the zinc and other reagents are arsenic and phosphorus free before adding the silver phosphide, hydrogen is liberated for some time and then the filter disk is examined. If this proves negative, the silver phosphide is then added and the flanges are put in place. The generator is allowed to run for about half an hour. The yellow color standards, when once prepared, are fairly stable and can be kept for several months if dry.

Other Uses for the Microchemical Flange.—The flanges described promise to be of great value for quantitative determinations in both gas and solution analyses where the intensity of a color reaction, which is proportionate to known amounts of the substance concerned, can be recorded.

Their use is being studied for the determination of sulfides, cyanides, alcohol, phenol, and other volatiles. For substances in solution which give brilliant graded colors with a detector, the flanges also have proved successful. A rapid method for the detection of lead in urine has been perfected and will be published later. The flange device was used in the Chemical Laboratory at Bellevue Hospital, New York City, while seeking more accurate and sensitive methods for the determination of arsenic. A paper on the subject is in progress and will be published from Bellevue Hospital.

Its broader application has been successfully demonstrated in the past few months at the Puerto Rican Department Laboratory.

SUMMARY

A brief review of the toxicology of phosphorus poisoning is given.

A new specific method for the quantitative microdetermination of phosphorus is described.

The principle involved depends upon trapping the phosphorus as silver phosphide, generating the phosphine by hydrogenation, and measuring the phosphine generated on a mercuric bromide filter disk. The color developed is a

*The flanges may be purchased cheaply from Eck & Krebbs or E. Machlett & Sons, both of New York City.

†Mercuric bromide sensitized paper is prepared by cutting round disks of Whatman No. 40 filter paper which are impregnated with 5 per cent mercuric bromide in 95 per cent alcohol for about five minutes. After shaking the droplets off, a disk is fastened between the flanges with a rubber band.

measure of the amount of phosphorus present and is determined by comparison with standards similarly prepared.

The microchemical flanges are a new device which may be used in a similar manner for other determinations, some of which have been mentioned.

QUALITATIVE STUDIES OF THE BILIRUBIN IN BODY FLUIDS*

II. A Comparison of the Direct Diazo Reaction by the Photoelectric Colorimeter, the Three Test Tube Method, and the Oxidation Test in Xanthochromic Spinal Fluid

Georg Lepehne, M.D., Boston, Mass.

IN A PRECEDING paper[1] qualitative studies of the bilirubin in blood serum by comparison of the direct diazo reaction using the photoelectric colorimeter, the three test tube method, and a new qualitative oxidation test for differentiation of the various types of jaundice were reported. In this paper similar studies concerning the bilirubin of xanthochromic spinal fluid will be presented.

METHOD

The xanthochromic spinal fluid was examined by the methods described in the preceding paper: the direct diazo three test tube method with use of caffeine-sodium salicylate,[2] the direct diazo photoelectric colorimeter method of Malloy and Evelyn,[3] and the qualitative oxidation test tube method[1] using a reagent consisting of nitric acid and sodium nitrite.

RESULTS

In 8 specimens of xanthochromic spinal fluid (hemorrhages, tumor, operation of the brain) the direct diazo photoelectric examination and the three test tube examination were done. In addition 7 specimens were examined by the three test tube method alone. In all 8 specimens the photoelectric direct diazo curves showed a definitely delayed, very slow ascending type of curve. On two specimens with the total bilirubin content of 2.28 mg. per 100 c.c. and 3.79 mg. per 100 c.c., respectively, in which the three test tube method revealed a biphasic-delayed direct diazo reaction, curves of delayed type were obtained too (see Fig. 1). These curves are very similar to those found in sera with delayed direct diazo reaction (hemolytic jaundice, jaundice of the newborn, etc.).[1] They are in clear contrast to the prompt direct curves obtained in serum of obstructive or

*From the Department of Medicine, Boston University School of Medicine.
Received for publication, August 13, 1942.

catarrhal jaundice. The indirect diazo reaction following the addition of methyl alcohol gave the usual steeply ascending curves (see Fig. 1). In order to express the significance of the direct curves in ratios the one-minute and the thirty-minute readings of the direct curves were compared with each other and with the one-minute and with the thirty-minute values of the indirect curves, as in the first paper (see Table I). On the average, the direct curve reached in one minute was 15.4 per cent, in thirty minutes, 36.2 per cent only of the total bilirubin content. The corresponding ratios in sera with delayed direct diazo reaction reported in the preceding paper were very similar, while the ratios in the prompt reacting sera of obstructive and catarrhal jaundice were entirely different.

TABLE I

COMPARISON OF QUALITATIVE AND QUANTITATIVE REACTIONS XANTHOCHROMIC SPINAL FLUID

5	192	0.6	27.1	35.5	54.0	50.1
6	264	1.0	18.7	29.5	26.0	48.0
7	1,500	2.3	10.1	15.3	30.7	32.9
8	710	3.8	4.3	6.1	26.9	16.7
Average			15.4	20.3	39.2	36.2

The three test tube direct diazo reaction was carried out in 15 specimens of xanthochromic spinal fluid, and in 13 specimens the reaction was definitely delayed. The first slight redness developed in 10 cases within an average time of five and one-half minutes. In 5 cases the red color had not developed within one hour. The change to purple color, described in the first communication, was not seen. The longest period of observation was two and one-half hours. The two specimens with the high bilirubin level (Table I, Nos. 7 and 8) showed by this method, in contrast to the delayed photoelectric curves, a biphasic-delayed direct diazo reaction. Immediately after addition of the diazo reagent a trace of redness developed, but the red color increased very slowly. The comparison of the three test tube method with the photoelectric method shows that the photoelectric readings are higher than one should expect according to the very slow development of the red color in the test tube method. This fact seems to depend on the greater accuracy of the photoelectric method to detect the color.

Vaughan and Hubbard[4] claim that every xanthochromic spinal fluid gives a "prompt" direct diazo reaction when the bilirubin content exceeds 0.3 mg. per 100 c.c. But one must consider that their expression "prompt" direct diazo reaction includes also biphasic-prompt and biphasic-delayed direct reactions[1] according to the usual nomenclature, so that their results are confusing. In our specimens a really prompt direct diazo reaction was not observed by our methods in spite of the fact that the bilirubin content was higher than 0.3 mg. per 100 c.c. (Table I). These authors also believe that the type of the direct diazo reaction in xanthochromic liquor with a bilirubin content below 0.3 mg.

per 100 c.c. depends upon the total protein content. In our cases with higher bilirubin values the total protein content ranged from 49 mg. to 3,720 mg. per 100 c.c. and did not influence the type of the reaction.

The oxidation test was made in 14 specimens of xanthochromic spinal fluid. In 12 cases the test was "negative" (a straw color developed or the color did not change at all). In the two specimens with higher bilirubin content, which gave a biphasic-delayed direct diazo reaction, the oxidation test was "diminished-delayed" (a slight yellowish-green color appeared twenty to thirty seconds after addition of the reagent). In order to control the oxidation test a drop of serum of obstructive jaundice was added to a specimen of colorless liquor. A real green color developed immediately ("prompt" oxidation test).

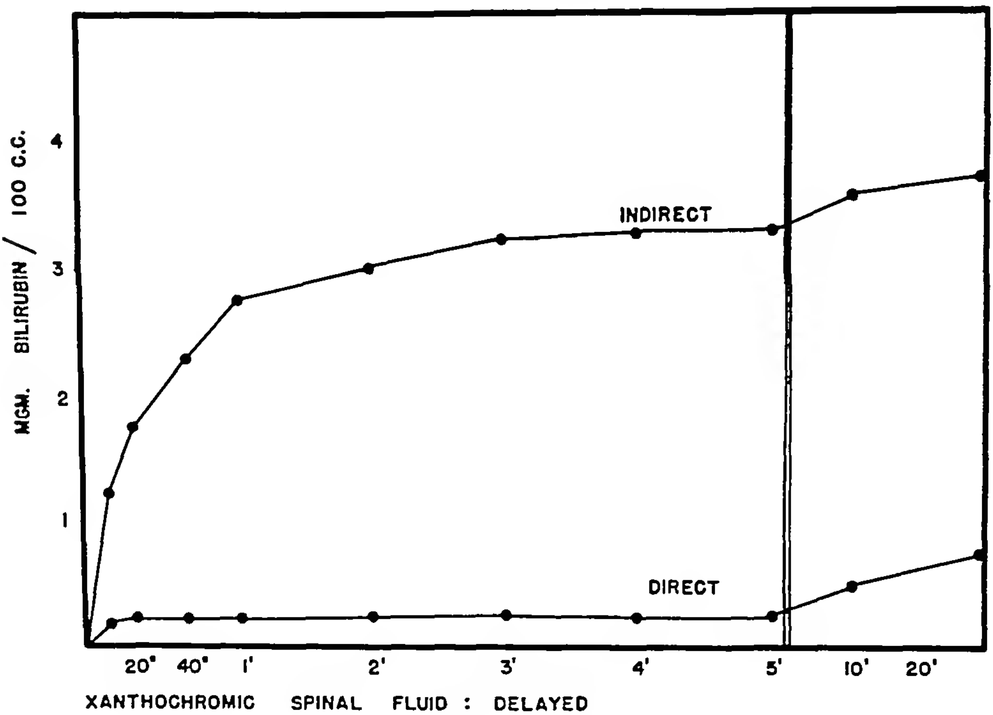

Fig. 1.—"Delayed direct diazo reaction" in a case of xanthochromic spinal fluid.

DISCUSSION

These examinations reveal that the bilirubin in xanthochromic spinal fluid gives the same qualitative reactions as the bilirubin in sera of hemolytic jaundice, of jaundice of the newborn, and of the nonhemolytic familial jaundice. These results support the theory that bilirubin giving such reactions is of anhepatic origin. Bilirubin in the blood of this type apparently did not pass the excreting liver cells. The liver cells change the direct diazo reaction from delayed to prompt (van den Bergh,[5] Aschoff,[6] McNee,[7] Lepehne,[8] Eppinger,[9] and other authors). The described examinations also reveal, as did the examinations on jaundiced serum,[1] that even in xanthochromic spinal fluid a really "negative" direct diazo reaction does not exist, when observation time is long enough. The direct diazo reaction can be, generally speaking, either prompt, biphasic, or delayed, but not negative.

SUMMARY

The bilirubin of xanthochromic spinal fluid was examined by the direct diazo three test tube method, by the direct diazo photoelectric method, and by the oxidation test. The direct diazo reaction was delayed or biphasic-delayed, and the oxidation test negative or diminished-delayed. The total protein content did not influence the type of the reaction. This bilirubin is of the same type as that in the blood serum in hemolytic jaundice and jaundice of the newborn.

A SIMPLE METHOD FOR DETERMINING PLASMA DENSITY AND PLASMA PROTEIN CONCENTRATION*

Eric Ponder, M.D., D.Sc., Mineola, L. I.

In the course of an investigation on water balance and plasma protein concentration I have had occasion to make large numbers of plasma protein determinations by a modification of the Linderstrøm-Lang method for measuring density, which is so convenient and accurate that it is worth while drawing attention to it.

The only apparatus required is a glass cylinder of 100 to 200 ml. capacity, graduated in milliliters. At least every 10 ml. graduation mark should run all around the cylinder, so as to enable one to avoid parallax in making readings. The cylinder is placed at eye level on a well-lit shelf shielded from drafts, in a room in which rapid changes of temperature do not occur. It is half-filled with a brombenzene-kerosene mixture of density 1.0485, made by mixing 35 ml. of brombenzene and 65 ml. of kerosene (density of brombenzene = 1.497; density of kerosene = 0.807). On top of this is layered about 50 ml. of a lighter mixture of density 1.0210, made up of 31 ml. of brombenzene and 69 ml. of kerosene. A rod, with a ring which just fits inside the cylinder at right angles to it, is moved gently up and down about a dozen times in the region of the

*From the Nassau Hospital, Mineola.
Received for publication, August 25, 1942.

interface between the heavier and the lighter fluids, and in this way a remarkably even gradient of density is produced, usually between the 20 ml. and the the 80 ml. marks on the graduation of the cylinder.

A series of standards are prepared from the commercially supplied potassium sulfate standard of density 1.0551[1] by the addition of distilled water in proportions indicated in Table I. These standards are kept in dropping bottles with well ground-in pipettes. A drop of each standard is dropped into the fluid in the cylinder, through which it descends until it reaches a level with a density the same as its own. The drop is formed on the end of the pipette, dipping below the surface of the fluid; on withdrawing the pipette, the drop breaks off. Its size is not very important, but 5 to 15 c.mm. is a convenient size. In this way the variations in the density gradient in the cylinder are marked off by the position of the six drops of known density, which correspond to six readings on the scale on the cylinder. In making the readings, care must be taken to avoid parallax. If the densities of the drops are plotted against their position on the scale, a remarkably good straight line usually results, showing that the density gradient is linear. Even if it is not, the graph can be used for finding the density of the gradient at any level. If the gradient changes, as it may on account of variations in temperature, etc., the positions of the standard drops change with it, and they always mark the six positions of their own densities.

TABLE I

D = 1.0551 ML.	WATER ML.	D OF MIXTURE	CORRESPONDS TO PROTEIN, GM. PER 100 C.C.
18.0	12.0	1.0330	8.89
16.5	13.5	1.0303	7.96
15.0	15.0	1.0276	7.04
13.5	16.5	1.0249	6.11
12.0	18.0	1.0221	5.17
10.5	19.5	1.0193	4.23

If a drop of plasma from heparinized blood is allowed to fall through the fluid in the cylinder in the same way, it will stop at a position in the density gradient, which corresponds to its own density. A reading of this position on the scale and reference to the graph for the positions of the standard drops will give its density immediately, and its protein content can be found from the density in the usual way from tables, or from a graph prepared by plotting the last two columns of Table I. Since the lipoids of the drop and the brombenzene and kerosene are not mutually altogether insoluble, the drop tends to sink slowly from the position which it first assumes, and so its position should be read after a standard time, e.g., one minute from the moment it is dropped into the cylinder. For the same reason, small drops are better than large ones, and 5 to 10 c.mm. is a convenient size. I use medicine droppers drawn out into capillary pipettes for forming the drops.

When some experience has been gained, the method will be found to give values for plasma protein concentration correct to ±0.1 Gm. per 100 c.c. This is not as high a precision as is claimed for the falling-drop method, but both methods have the weakness that what they measure is plasma density, which depends on protein concentration only when the lipoid content is constant, and

so a precision sufficient to measure ±0.0003 in the figure for density is enough for all clinical purposes. The method is convenient in practice, and at least 20 determinations can be made before the fluids need replacement and a new gradient has to be formed. Unwanted drops can be removed by touching them with a small piece of wet filter paper attached to the end of a capillary pipette. The drops adhere to the paper and can be pulled up out of the brombenzene-kerosene mixture.

MEDICAL ILLUSTRATION

A SIMPLE TECHNIQUE FOR TIME LAPSE CINEMICROGRAPHY*

Adrianus Pijper, M.D., D.Sc., and Laurie B. Poole
Pretoria, South Africa

PURPOSE OF THE METHOD

New methods lead to new findings. Cinematography in many laboratories is still a novelty. Photographing the subject through a microscope at ordinary speed may show nothing beyond what the eye has noticed already, although even here the film often records something that has escaped detection by the eye alone. Slow motion cinemicrography analyzes movements too rapid to be observed by the human eye. In time lapse cinematography and cinemicrography we have methods that make visible what no human eye has the patience or the facility to observe.

Time lapse cinematography is the process of taking pictures at a slower rate than the one at which they are eventually projected. Movements too tedious or too slow to be watched can thus be condensed into processes which are easily followed on the screen. Audiences are familiar with the method as applied, for instance, to the unfolding of a flower. In time lapse cinemicrography the same method is used but the pictures are taken through a microscope.

New methods can only bring results in proportion to the frequency with which they are used. Time lapse cinemicrography so far has not been applied widely. The hesitation to put into regular use a method so full of possibilities is largely caused by technical considerations. We believe that the technical difficulties of the method are overestimated. Considerable work in this field has been done by Comandon. Splendid apparatus has been built by Rosenberger,[5] Harris,[2] and by Roger,[6] but we feel that excellent results can be obtained by much simpler methods. In this paper we wish to show that time lapse cinemicrography is within the reach of most biologic laboratories. Our apparatus has been built by the simplest possible means and can be set up on an ordinary laboratory bench.

SPEED CONTROL

The chief part of the speed control is an ebonite disk, measuring $6\frac{1}{2}$ inches in diameter (Figs. 1*A* and 2*A*), which revolves once a minute. It is driven by an ordinary electric clock motor (Fig. 2*B*), which is operated on 60 cycle alternating electric current. There are 60 small equidistant holes drilled through this disk on a circle near the periphery. Tapering steel pins can be pushed into these holes. As the disk rotates, these pins make electric contacts which activate the shutter between the lamp and microscope, and also drive the camera and a counter.

*From Dr. A. Pijper's private laboratory.
Received for publication, July 20, 1942.

It is obvious that the longest lapse of time available with this apparatus is one minute, and the shortest time is a second. In addition, one can work at any number of seconds in between these two values by changing the number of pins on the disk. Up to the present we have found this time control ample for our requirements.

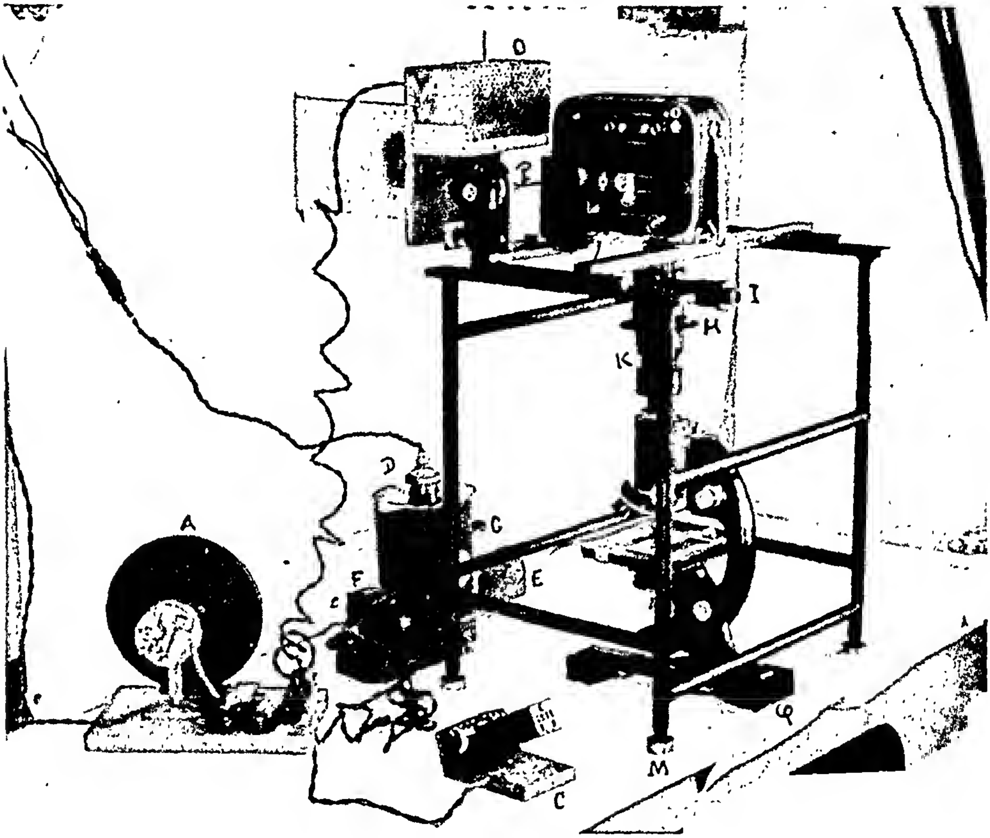

Fig. 1.—Side view of the apparatus.

A diagram of the wiring is given in Fig. 3. The steel pins make contact by depressing the metal tongues as they go through the lowest point of their rotation. The tongues are placed on top of one another and are arranged so that the one that activates the shutter between the lamp and microscope keeps this shutter open long enough for the tongue that works the camera to expose the film. The counter (Figs. 1*C* and 2*C*) is added in order to check the number of exposures made but is not an essential part of the apparatus.

SOURCE OF LIGHT

An Ediswan Pointolite lamp of 100 C. P. is used (Figs. 1*D* and 2*D*). A stronger lamp would be better but is not procurable under present conditions. An arc lamp, of course, is too unsteady for this kind of work. The shutter between the lamp and microscope (Figs. 1*E* and 2*E*) is made of light metal and is essential because it prevents exposure of the microbes to continuous light. It is lifted by a solenoid (Figs. 1*F* and 2*F*) and drops by its own weight. The shut-

ter can be kept raised permanently by pushing a lever (Fig. 1*G*) to the left. This is useful for making adjustments to the microscope.

THE MICROSCOPE

We use the large Zeiss stand FCG, as shown in Figs. 1 and 2, but any other heavy stand will serve. Since the dark field is the method of choice for this class of work, we use the Siedentopf cardioid condenser. To date we have worked mainly with fungal material, and a suitable combination of lenses was found in the Zeiss apochromat objective ×60 with iris and the Zeiss compensating eyepiece ×7. We have also used the Zeiss compensating eyepiece ×10. The distance between eyepiece and film is about 15 cm. These combinations resulted in magnification on the film of ×200 and ×310, respectively.

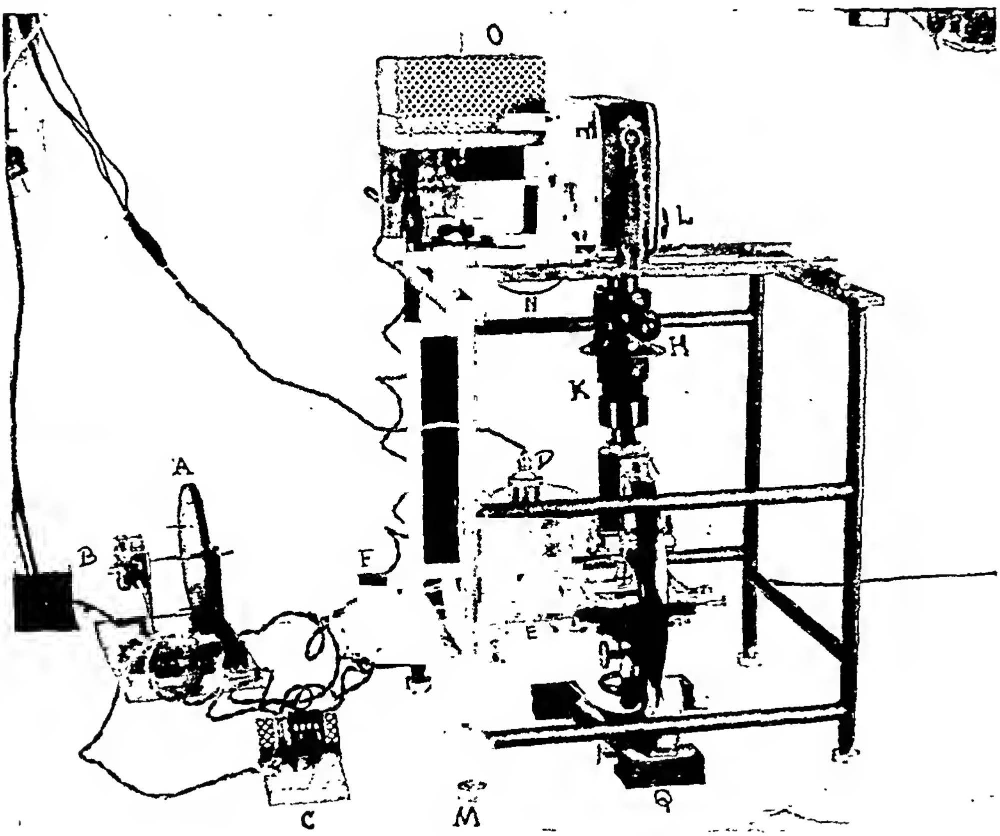

Fig. 2.—Front view of the apparatus.

THE PREPARATION ON THE SLIDE

For studying the growth of monilias, yeasts, and other fungi we place a small drop of a fairly thick suspension of spores on a microscope slide. A drop of melted Sabouraud agar cooled down to about 50° C. is added, and a cover slip is dropped on rapidly. Previous setting of the agar and moving of the cover slip must be avoided, since these lead to the formation of channels in the agar filled with thin fluid in which the spores swim about instead of lying still in solid agar. Petroleum jelly is applied around the cover slip. The microscope is then adjusted and the proper field is found in the usual way.

THE CAMERA

Our camera is a standard Movikon, with the lens removed and replaced by the beam splitter made by Zeiss for such purposes (Figs. 1*H* and 2*H*). Of course, any other make, or even a homemade one, will do. The one we use gives an additional magnification which is helpful in focusing. A suitable cap should be placed over the eye lens of the beam splitter (Fig. 1*I*), otherwise, as Barnard has pointed out,[1] extraneous light may reach the film. A lightproof connection between the microscope and camera is provided by a black velvet skirt (Figs. 1*K* and 2*K*) which fits into the sleeve around the eyepiece. The microscope and camera should not touch one another.

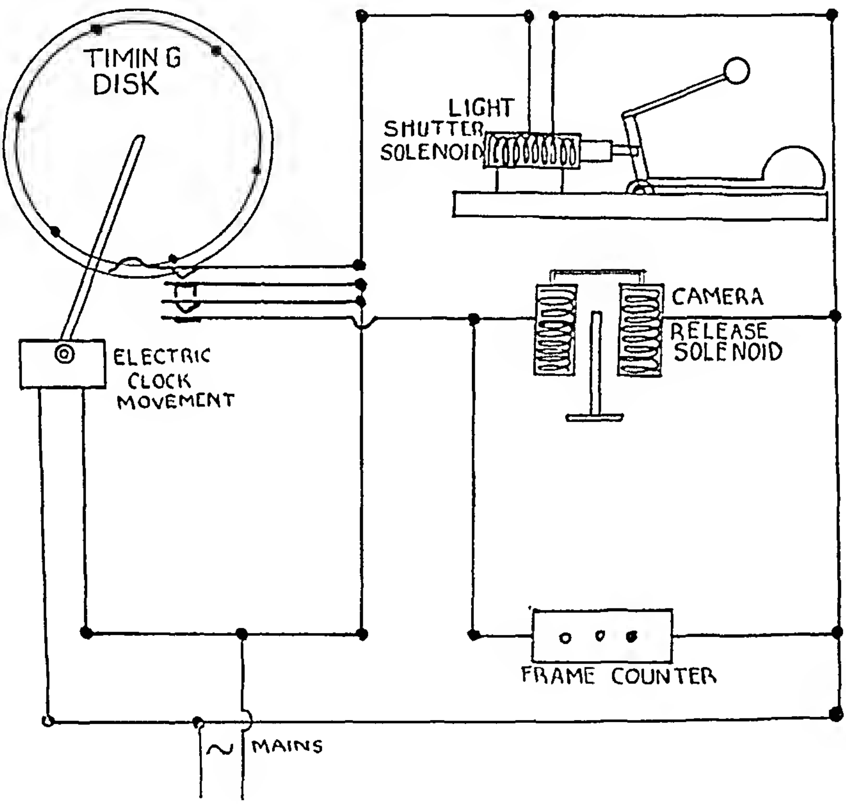

Fig. 3.—Wiring diagram of the apparatus.

The camera is supported on two horizontal flat iron bars, as seen in Figs. 1 and 2. It rests only on the front one and the posterior bar carries an upright piece of metal to which the camera is clamped by means of a clamping screw. This screw threads into the hole at the base of the camera provided for that purpose. The two horizontal flat bars also merely rest on the top of the iron stand which surrounds the microscope, as is shown in Figs. 1 and 2. From these illustrations it is seen that the camera can slide forward and backward with the two flat bars along the two round iron bars included purposely. This is necessary for accurate centering over the microscope. Slight movements to the side during centering are best executed by changing the position of the microscope. Centering is done through the beam splitter, but the beam splitter itself should be centered by looking at the picture on the film through the focusing magnifier which belongs to the camera (Fig. 2*L*).

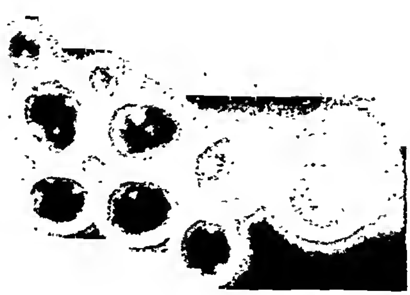
The stand around the microscope consists of four uprights, which are connected by sufficient crossbars to keep the structure rigid and to allow access to the microscope. The microscope can be handled easily with the stand in place. It can, however, be removed and be replaced again by means of the four brass cups (Figs. 1*M* and 2*M*) into which the conical ends of the four uprights fit tightly. These cups are screwed to the bench.

The Movikon camera possesses the essential single picture mechanism and is conveniently set in motion by means of a wire release (Fig. 2*N*). This wire release is activated through a solenoid (Figs. 1*O* and 2*O*), which is attached to a wall bracket and does not touch the stand or the camera.

Fig. 4.

Fig. 5.

Fig. 6.



Figs. 4, 5, and 6.—Frames from a film of budding Monilia cells.

The single picture mechanism of this camera does not allow an exposure longer than 1/25 second. This is ample for ordinary work but is insufficient for cinemicrography with a light source of 100 C.P., unless the lowest magnifications are used. In looking for a means to lengthen the exposure, we found that the Movikon camera has a shaft or rewinding spindle for making mixes. This shaft protrudes through the housing and makes a half revolution during each exposure. It was decided to slow down this shaft by attaching to it the dial

of an automatic telephone. The exposure was thus increased. Such a dial moves at a fixed speed which is controlled by a built-in governor. In Figs. 1 and 2 the dial is shown attached to an upright that is fixed to the posterior horizontal bar, to which the camera is attached in a similar manner. The dial center spindle is connected to the extended shaft of the camera by a universal coupling, a length of shafting, and a screw which is fitted onto the splined end of the coupling shaft. The splines and screw allow the dial to be disconnected quickly for winding the camera, but this cannot be done with the connection in place. By such an arrangement we found that the shutter action of the single picture mechanism was slowed down to ⅕ second.

The use of the camera spring for moving the film eliminates the geared electric motors which are usually deemed essential for time lapse cinematography. Our plan prevents their vibrations. The disadvantage of this method is that the spring must be wound at regular intervals. One winding suffices for 20 feet of film, and at a speed of one picture a minute each winding lasts ten hours. Frequent inspections of the field are necessary to make sure that nothing untoward is happening. Therefore, the occasional winding of the spring is of no great consequence.

VIBRATION

The danger of spoiling cinemicrographic pictures by vibration is often overrated. For speeds of 16 frames a second, for instance, or even 64 frames a second, we have shown previously that it is quite safe to place both the camera and microscope on the same iron optical bench,[3, 4] provided the eyepiece of the microscope does not touch the camera and the spring of the camera is used to move the film. For our time lapse cinemicrography with its longer exposures we found it safe to place the whole outfit on an ordinary wooden laboratory bench, if the precautions mentioned were observed. The weight of the camera with its attachments holds it steady. In addition, the camera with the posterior horizontal bar and the telephone dial can be lifted up and put aside as one piece by simply undoing the wire release from the camera. The anterior horizontal bar is loose and thus the microscope is ready for ordinary use at a moment's notice.

There is still another feature to explain. We prevent vibration of the microscope by placing its base on soft rubber pads (Figs. 1*Q* and 2*Q*). It is held in place by a long fastening screw which goes through a hole in the wooden bench and reaches the base of the microscope from underneath. The hole through the bench is lined with soft sponge rubber, and there is a rubber washer separating the head of the fastening screw from the bench beneath. This arrangement allows slight movements of the microscope from side to side and assists in centering.

FILMING OF BUDDING MONILIA CELLS

By means of the apparatus described we have made a film of budding Monilia cells, from which frames are reproduced in Figs. 4, 5, and 6. In the film the budding cell of Fig. 4 can be seen to produce by repeated budding and separating, first, the three cells of Fig. 5, and finally the seven cells in Fig. 6. It shows that before budding takes place there is great activity of the particles that can be seen in the cells. Usually this is near the part of the wall that is

going to break down. The yielding of the cell wall is a surprisingly sudden process compared with the following development of the bud. It is again accompanied by great activity of the particles, which can be seen making their way into the new cell. As a rule, it is possible to keep in focus the communicating opening between the two cells. The cell wall of a new cell is at first much thinner than later. As soon as it reaches the thickness of the old cell, the opening closes and often the cells separate with a sudden jerk.

SUMMARY

A technique is described which enables biologic laboratories possessing ordinary equipment and the services of a skilled technician to make time lapse cinemicrographic 16 mm. films. The apparatus is put together from simple materials, can be used on an ordinary wooden laboratory bench, and can be assembled and taken apart in a few moments, so that the microscope remains available for ordinary use.

THE MINIATURE CAMERA APPROACH TO VISUAL EDUCATION*

George Fiske Johnson, Ph.D., State College, Pa.

IT IS NOW almost six years since the miniature camera first attracted the serious attention of educators in the United States as a new approach to effective visual instruction. The growing enthusiasm among the professions for this type of camera and its products as an aid in teaching and in recording scientific data is revolutionizing the photographic and visual aid programs of many institutions.

The possibilities of the miniature camera and related equipment in photographing medical subjects, especially in color, have been reviewed previously in this JOURNAL. Jeter and Hull[1] pointed out several years ago the value of using 35 mm. color film in miniature cameras as a means for securing 2 by 2 inch slides for illustrative purposes. "The pathologist and the pathologic department of every hospital should assume teaching responsibilities," they wrote. "We believe color photographs, as carried out by the simple, inexpensive method described, is now practical and, furthermore, adds greatly to the facilities of teaching."

*From the Agricultural Extension Service of the Pennsylvania State College.
Received for publication, July 21, 1942.

Tomlinson[2] recently called the attention of the medical profession again to miniature cameras, 35 mm. color film, 2 by 2 inch slides, illuminators for displaying color transparencies, and especially their application to photomicrography.

DeLucchi,[3] reporting on a survey of 55 medical school hospitals, clinics, biologic photographic departments, and medical laboratories, writes: "There is a very noticeable increase in the use of the smaller 2 by 2 inch Kodachrome slides (photographed usually in miniature cameras). . . . A numerical checkup will show that the demand has been so great that the smaller-sized slide is definitely and rapidly becoming part of the routinely produced material in a majority of biological laboratories. The field of photography as used to illustrate surgical procedure has also been invaded by the 2 by 2 inch Kodachrome slide. More and more this small size slide is being used to augment 16 mm. Kodachrome motion pictures, and in one department has replaced the motion picture to a large extent. It is felt that a series of pictures taken during the process of an operation are excellent for teaching. The cost of such a series is less than a motion picture covering the same procedure. It is to be noted that three out of four new photographic laboratories (less than one-year old) are using 2 by 2 inch slides. . . ."

Other writers, especially in the field of biology, such as Brubaker and Holinger,[4] Waller and Breedis,[5] Footer,[6] and Koch,[7] have recognized this new trend in photography and visual education and have recorded many valuable ideas and experiences.

I have been associated with the development of a visual aid service in the division of agricultural and home economics extension at the Pennsylvania State College for the past seven years. This service employs 200 county farm and home economic representatives and state-wide subject matter specialists who conduct demonstrations on better farm and home economic practices and assist with 10,000 educational programs in rural communities annually.

Our enthusiasm for the miniature camera was generated in 1937 when it was demonstrated that a $15 camera (more expensive now) taking the new 35 mm. color film could produce reasonably true-to-color transparencies at a film cost of 15 cents each. We saw in this simple, inexpensive equipment the means of improving the photographic and visual aid program for our workers. The reasons for this were: (1) the equipment was light and easily carried; this was an extremely important advantage because our workers were traveling educators; (2) the equipment was less expensive than that available in the past; (3) the miniature camera loaded with color film was more foolproof and more exhilarating in results attained than larger cameras with black-and-white film; (4) the unit cost of the visual aids secured was substantially less than that prevailing with either the standard lantern slide or 16 mm. motion pictures. We now have in our organization 107 miniature (35 mm. film) cameras costing from $15 to $175 each.

Slides, 2 by 2 Inches, Lead as Visual Aids.—How revolutionary recent improvements in visual aids have been in our case can be cited specifically. The number of standard-sized black-and-white lantern slides in use decreased from 5,000 in 1935 to fewer than 500 (used infrequently) in 1942, and in their place have come almost 25,000 of the new 2 by 2 inch slides taken with miniature

cameras, mostly in natural color. We produced more than five times as many color slides in four years (1937 to 1941) as standard-sized black-and-white slides in twenty years (1917 to 1936). Even more significant was the fact that a complete equipment change requiring the adapting of old projectors or the purchase of new projectors was necessary to effect this change-over in the type of slide used.

Fig. 1.—County Agricultural Agent Russell M. Smith, Forest County, Pa., with a portion of the 800 2 by 2 inch slides which he has produced and utilized more than 300 times in the past four years on a total equipment and film expenditure of less than $225.00.

Screens for showing pictures changed in character completely during this seven-year period. Most screens in 1935 were white cloth on which color slides would not show up clearly in the daytime in rooms that could not be darkened completely. Only one solution could be found and that was to buy the beaded surface type of screen. A few demonstrations were extremely convincing, so that today we have 82 beaded surface screens, 77 in county offices and 5 in the State College office. Each county has at least one of these screens, and 11 counties have two each. The folding base tripod screen is most popular.

The trend in the use of visual aids since 1935 is shown in Fig. 3. The use of 2 by 2 inch slides has increased from zero in 1936 to almost 50 per cent of all meetings in 1942; 16 mm. movies (mostly silent), of which we made over 150 reels, gained from 5 to 15 per cent; large lantern slides and film strips decreased from 25 to 1 per cent; visual aids other than projected pictures dropped slightly from 30 to 25 per cent; and meetings with no visual aids decreased from 35 to 10 per cent. It will be observed that the 2 by 2 inch slides are used in a larger percentage of meetings today than all forms of projected pictures employed only seven years ago.

The mistake is made of regarding the 2 by 2 inch slides as nothing more than the large lantern slide in a new dress. This transparency is a *new visual medium*. Because of its low film and processing costs each step in a process

can be recorded economically. Furthermore, the mechanics of the camera are so simple that a sequence of pictures can be taken quickly. In this sense the miniature camera is a cross between the motion picture camera and the more cumbersome cut film or film pack reflex or view camera. Likewise, when skillfully used in the lecture room the resulting pictures retain all advantages of the slide medium while acquiring some of the advantages of the motion picture.

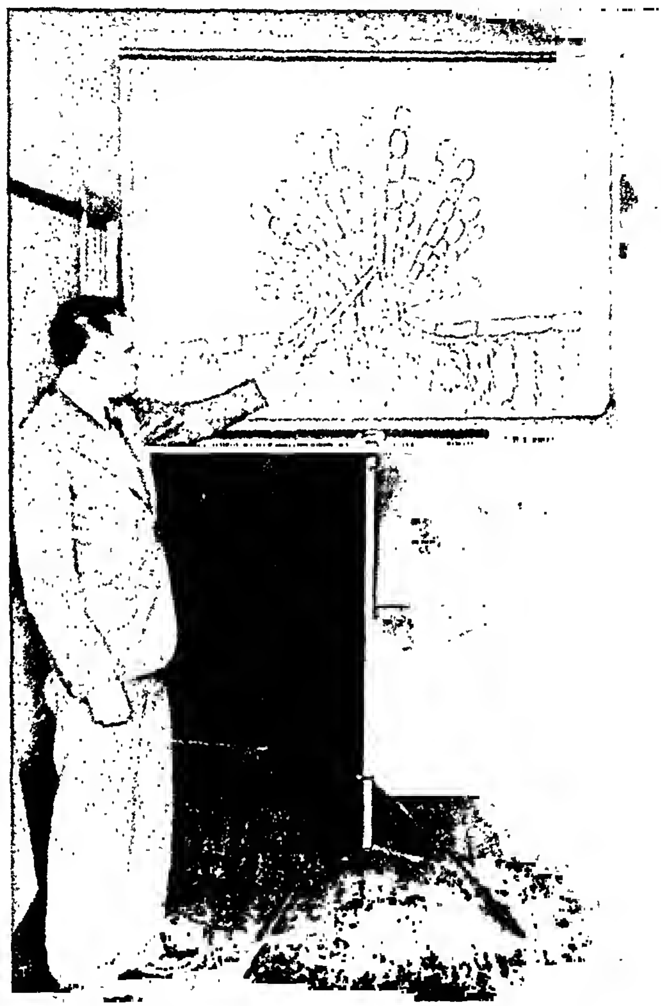

Fig. 2.—The folding base tripod beaded surface screen in use. Note that it can be elevated to shoulder height.

Advantages of Slides over Motion Pictures.—Although physical completeness is attained with a well-photographed motion picture of an operation or method demonstration, this does not mean that completeness of understanding is always reached, even when fully explained. The skillful lecturer can often take a well-photographed series of slides of this same operation or method demonstration and secure more complete and lasting understanding of the operation because: (1) the most critical stages or steps in the operation can be retained clearly on the screen for an indefinite period for detailed explanation;

(2) contrasts and comparisons can be made most easily and, if necessary, remade to fit the mental response of the audience; (3) in subsequent discussion any one scene can be selected quickly and returned to the screen; (4) the still transparencies can be placed in an illuminator and the entire sequence can be studied at one time. Of course, the ideal is a motion picture and a series of still transparencies of the same operation. This is often impractical, however, due to the cost or the impossibility of repeating the exact operation.

To accomplish the most with slides, we find that a 300 or higher wattage projector with forced draft or other means of thorough ventilation is necessary. This type of equipment enables a lecturer to retain a slide in the projector indefinitely without damage and still secure good projection with sufficient light in the room for note taking.

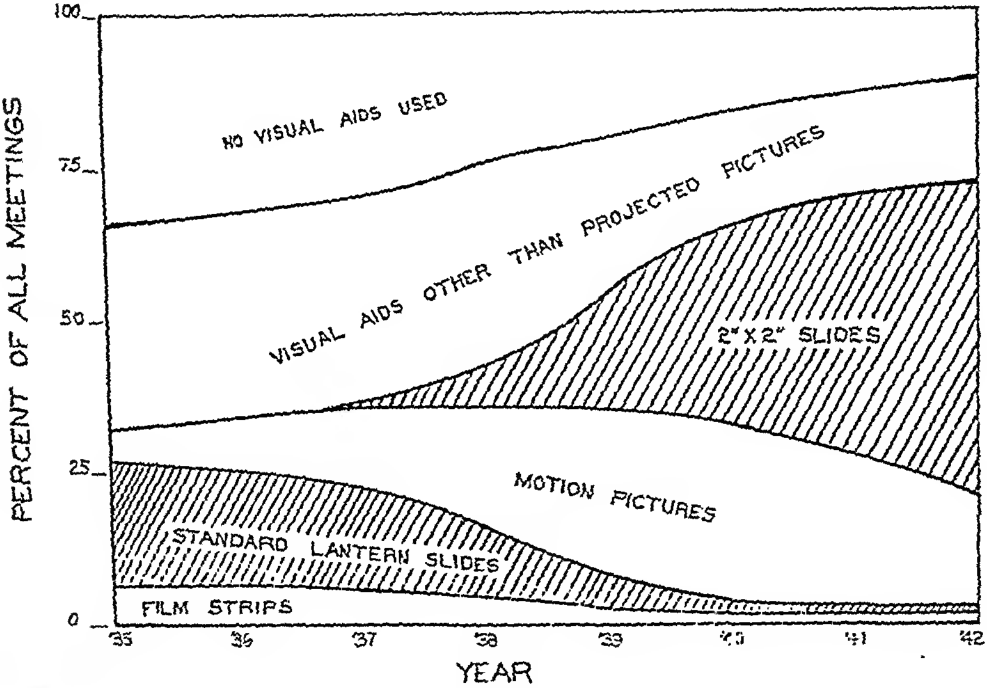

Fig. 3.—Trend in the use of visual aids in indoor subject matter meetings conducted by the Pennsylvania Agricultural Extension Service, 1935 to 1942.

One important factor in our plan is that assistance and encouragement are given for workers to produce their own visual aids. The development of the miniature camera, color film, and the exposure meter has been a great stimulus in this direction. The miniature camera, as we use it, is a lantern slide camera because color film is used, and when the shutter is clicked, a lantern slide is produced. This so simplifies the procedure of making lantern slides that over 80 of our workers are successfully producing these slides at the rate of 5,000 a year.

MINIATURE REFLEX CAMERA FOR PHOTOMICROGRAPHY

We find the 35 mm. film size reflex camera extremely practical for photomicrography. In this type of photography we employ a carbon arc light for illumination with either transmitted or reflected light, depending upon the

MINIATURE REFLEX CAMERA FOR PHOTOMICROGRAPHY

We find the 35 mm. film size reflex camera extremely practical for photomicrography. In this type of photography we employ a carbon arc light for illumination with either transmitted or reflected light, depending upon the

subject. The camera setup is as follows: The lens of the camera is replaced with a hinged microscope adapter which slips over the top of the microscope. The hinge enables the technician to swing the camera aside while searching for the proper field to be photographed. When this is determined, the camera is returned to the top of the microscope and focusing is completed through the

Fig. 4.

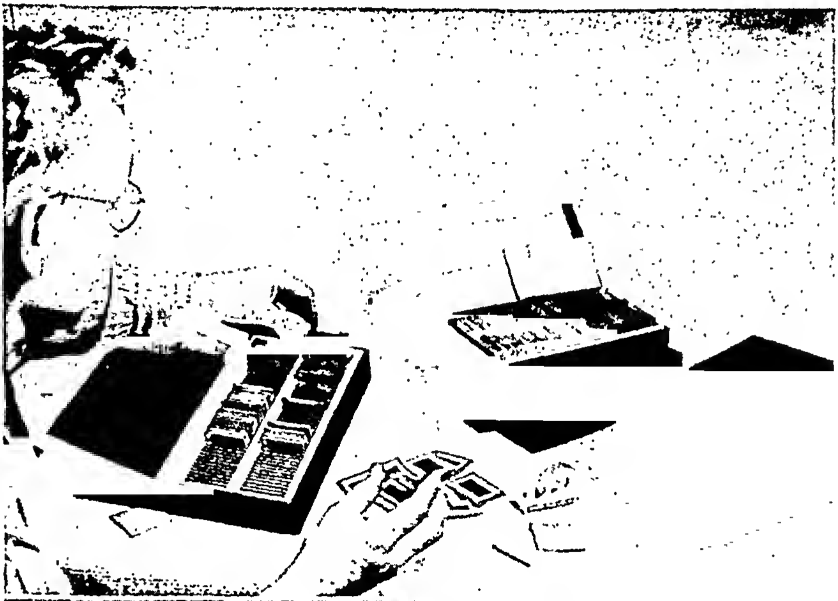

Fig. 5.

Fig. 5.—The projector strip method of filing 2 by 2 inch slides.

reflex viewer. By using type A Kodachrome film and the carbon arc light, our experience indicates an exposure from one-tenth second to three seconds, based upon various light factors. We normally take three exposures, such as one-tenth, one-half, and one second, one-half, one, and two seconds, or one, two, and three seconds, depending upon our judgment of which light group fits the subject.

Fig. 6.

Fig. 7.

Fig. 6.—Sliding panels in a metal cabinet provide an efficient file for 2 by 2 inch slides.
Fig. 7.—Using the illuminator to arrange a series of slides for an illustrated talk.

The 2 by 2 inch Kodachrome transparencies can be duplicated successfully by the manufacturer at a cost of 25 cents each. The best duplicates are made from correctly or slightly underexposed views. Overexposures do not duplicate well. Color prints, measuring $2\frac{1}{4}$ by $3\frac{1}{4}$ inches, can be made from the transparencies by the manufacturer at a cost of 75 cents each. A 5 by $7\frac{1}{2}$ inch

size is made for $3.50. Fairly close-up subjects with distinct lines photographed on 35 mm. Kodachrome can often be converted successfully to a 5 by 7 inch black-and-white negative for a monochrome contact print of publication quality.

EFFICIENT FILES A NECESSITY

Since many of our departments and county offices have from 200 to 800 of the 2 by 2 inch slides, efficient filing has become essential to the best utilization of these vast visual aid resources. We have several types of files in use: (1) the box type with partitions for individual slides; (2) the panel type in which slides are filed in panels or cardboard holders and viewed by holding them before a lighted background; (3) the projector strip file in which slides are held in a cardboard projector strip that is used as a slide carrier in the projector (see Figs. 4 to 6).

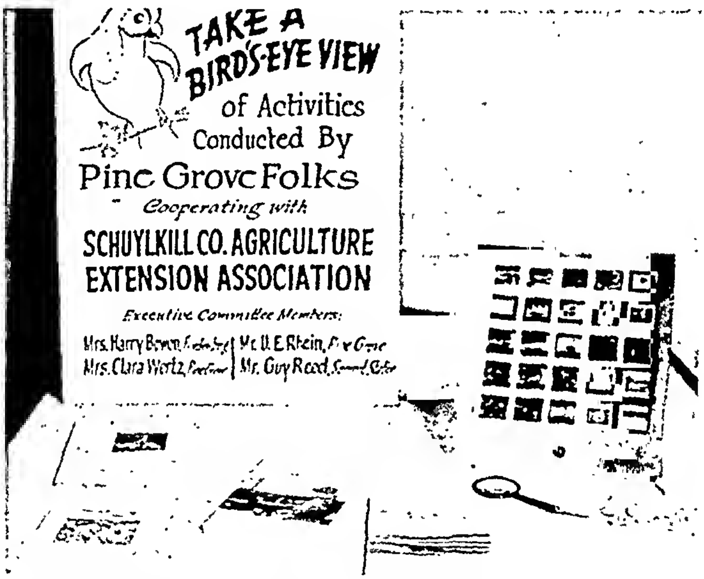

Fig. 8.—Inexpensive, simple and yet an extremely effective local community exhibit based upon the use of 2 by 2 inch slides in an illuminator. Note the magnifying glass on a string for use in looking at slides.

In general, a satisfactory file has the following characteristics: It is convenient to get slides into and out of the file with a minimum amount of time; it is not so complicated that great effort is required in keeping the file up to date; it is flexible in compartment spacing and new slides can be added without the continual handling of old slides. The object of an efficient slide filing system is to reduce slide handling and effort in filing to a minimum and at the same time make it possible to organize an illustrated talk quickly with all the material at hand. We have found that our workers who make the most of color slides in teaching are likely to accumulate at least 300 slides. To be most useful these must be in an efficient file. The cost of equipment for filing varies from 2 to 7 cents for each glass-covered slide, depending upon the system used.

THE ILLUMINATOR IN USE

In addition to a well-kept file of slides we find a relatively new piece of visual aid equipment called the *illuminator* useful in organizing a series of

these slides for lecture purposes. In simple terms, the illuminator is a ventilated boxlike structure with a white interior containing a 60 watt ordinary light bulb. The surface to be used for illuminating slides is of opal or ground glass. The slides are assembled on this surface.

With a 25 capacity slide illuminator available it is relatively easy to organize a series of slides for a lecture (Fig. 7). This piece of equipment eliminates the need of a preliminary showing of the slides on the screen, and it has the advantage of all slides being in view at one time. A magnifying glass can be used to enlarge the picture, if desired. Furthermore, we find the illuminator filled with color slides useful as the central feature of simple, inexpensive exhibits as shown in Fig. 8. In this we recognize the natural color slide as something more than a lantern slide to project onto a screen.

In our work we find a number of advantages in illuminated slides over projected pictures. The pictures can be viewed clearly in average indoor light without darkening the room. The need of carrying projection equipment and the difficulty of setup in small quarters filled with people are eliminated. Besides, a series of slides can be viewed and studied individually or as a sequence with all slides continually in view. On the other hand, the use of the illuminator is limited to situations where only a few persons look at the slides at one time, and it is impossible to show all types of views with equal effectiveness.

THE FUTURE

The 2 by 2 inch slide is definitely established as a visual aid medium of vast possibilities. As professional workers become more familiar with its many advantages the scope of its usefulness should continue to increase. It is likely to establish itself as an important supplement to the motion picture. For persons and institutions with limited budgets it will of necessity become the visual aid medium of primary consideration.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

TUBERCULOSIS, Pulmonary, The Weltmann Reaction, Owen, W. F., Jr., and Van Ordstrand, H. S. Cleveland Clin. Quart. 9: 135, 1942.

The Weltmann coagulation band was determined in 85 normal persons and a remarkably constant result was obtained, i.e., 6 to 6½.

In 75 cases of pulmonary tuberculosis, followed for a period of three to four months, an attempt was made to define how closely the coagulation band reflected the clinical picture and whether there was any correlation between the band and the sedimentation rate. In this group of 75 cases, 25 were chronic, arrested inactive cases, and in these the Weltmann reaction consistently showed a "shift to the right" and was a better indication of the clinical status than the sedimentation rate. In the remaining 50 cases the Weltmann coagulation band followed the clinical picture in 32 cases, or only 64 per cent, while the sedimentation rate was a good index in 40 cases, or 79 per cent. When the cases were divided into far advanced and minimal, it was shown that in the 27 far-advanced cases the Weltmann reaction was reliable in only 50 per cent as compared with 84 per cent with the sedimentation test. In the moderately advanced group of 20 cases, the sedimentation rate showed 60 per cent reliability and the coagulation band 80 per cent. There were only three minimal cases studied; the sedimentation rate was of no value in any while the Weltmann test was reliable in all.

Neither the Weltmann reaction nor the sedimentation rate is completely reliable or infallible in the diagnosis and prognosis of pulmonary tuberculosis. In these cases the sedimentation rate has been a somewhat better index of the clinical status of the patient. In doubtful cases it may be of value to do both tests.

In the chronic, arrested, inactive cases the Weltmann reaction consistently showed a "shift to the right" and was a better indication of the clinical status than the sedimentation rate.

There is no definite correlation between the Weltmann coagulation band the sedimentation rate.

PNEUMONIA, Capsular Polysaccharide in the Blood of Patients With Pneumococcic, Bukantz, S. C., deGara, P. F., and Bullowa, J. G. M. Arch. Int. Med. 69: 191, 1942.

Systematic determination of capsular polysaccharide, agglutinin, and precipitin titers were made on samples of blood of 135 patients with pneumonia caused by pneumococci of types I (32 cases), II (4 cases), III (40 cases), IV (1 case), V (9 cases), VII (33 cases), and VIII (16 cases) in a series rotated for treatment with sulfapyridine, with serum or with the two in combination.

Capsular polysaccharide was detected in the blood of 16 patients, or 11.8 per cent of the entire series. Eleven of the 16 had type III, 3 had type VII, and one had typo VIII pneumococcus pneumonia.

There was a significantly greater incidence of positive reactions for circulating capsular polysaccharide in the older age group, a tendency to greater incidence with increasing duration of disease, and an equal sex incidence.

The mortality for the patients in whose blood capsular polysaccharide was present was 62.5 per cent, while the mortality for all the patients with bacteriemia was only 29 per cent, and the mortality for the entire series was 11.8 per cent. The mortality for the patients without bacteriemia and without capsular polysaccharide in the blood was only 3 per cent.

Of the 10 patients whose serum gave a positive reaction for capsular polysaccharide and who were treated with sulfapyridine alone, 6 died. The illness of the 4 patients recovering

under sulfapyridine therapy alone ran a prolonged course, with a tendency to recurrence of fever, slow disappearance of capsular polysaccharide from the blood, and failure to produce antibody.

Of the 5 patients whose serum gave a positive reaction for capsular polysaccharide and who were treated with both sulfapyridine and serum, 3 died; two of these did not receive serum and sulfapyridine simultaneously, and the third received insufficient sulfapyridine. The 2 patients recovering after simultaneous serum and sulfapyridine therapy made much more satisfactory clinical responses. The sixteenth patient in whose blood capsular polysaccharide was detected died after treatment with serum alone.

CARTILAGE, A New Histochemical Reaction With High Specificity for Cartilage Cells, Hass, G. M. Arch. Path. 33: 174, 1942.

The fresh tissues, except when decalcification was necessary, was cut into sections with a freezing microtome set at 15 to 20 microns. The sections were divided into lots for preservation in water, alcohol, and solution of formaldehyde U.S.P. The sections in distilled water were subdivided into three groups. One group was used for immediate study. Sections of the second group were mounted on glass slides and dried rapidly in a vacuum desiccator. The third group of sections was placed in the refrigerator at 5° C.

It was impossible to obtain suitable sections of fresh bone, although osseous tissue often remained so attached to epiphyseal cartilages at the primary zones of ossification that a few observations could be made. Decalcification of formaldehyde-fixed or fresh tissue with 0.5 molar hydrochloric acid was necessary before good sections of bone were obtained.

Sections of the designated organs and tissues were exposed to the action of numerous combinations and concentrations of 0.5 molar hydrochloric acid, 0.5 molar sodium hydroxide, 0.20 molar sodium nitrite and 0.04 molar crystal violet. Optimum conditions for obtaining the desired reaction were as follows: A solution containing 10 c.c. of 0.5 molar hydrochloric acid, 4 c.c. of 0.04 molar crystal violet, and 1 c.c. of 0.20 molar sodium nitrite, or multiples thereof, was prepared. The reaction was allowed to proceed for forty-five minutes at room temperature. Then 0.5 molar sodium hydroxide was added slowly until a delicate fluorescence developed. Seven to 8 c.c. were required, the quantity being so adjusted that a fine precipitate formed in the reaction mixture about ten minutes after appearance of the fluorescence. After addition of the alkali, 20 c.c. of the reaction mixture was transferred to each of a desired number of 25 c.c. beakers. One section of tissue was placed in each beaker and kept there throughout the fifteen to twenty minutes required for the formation of a precipitate. After precipitation was complete, ether was poured on the surface of the solution. The sections were withdrawn from the reaction mixture through the ether layer, washed in distilled water, floated onto glass slides, blotted with filter paper, stained with aqueous hematoxylin, and mounted in glycerogelatin under a cover slip.

Similar results were obtained when the sections had been affixed to glass slides by preparatory desiccation in vacuo. When available in this form, the tissues were more easily handled than when they were floating in the solution.

This standard method was varied so that some data might be gathered with respect to the action of alcohol, acetone, ether, and 0.5 molar hydrochloric acid on the capacity of the tissue to react and on the stability of the reaction product once it had formed. By use of these reagents it was possible to make a microscopic study of cells prior to running the reaction, after a positive reaction had been obtained, and after eliminating all traces of the positive reaction. In other attempts to determine the nature of the reactive cytoplasmic component, the carmine stains for glycogen, the perosmic acid stain for lipids, the sudan IV stain for neutral glycerides, and the hematoxylin-eosin stains were prepared.

A positive reaction consisted of an aggregate of particles in the cytoplasmic area of a cell. The particles, which varied from 1 to 3 microns in diameter, were yellow, refractile, and discoid or spherical. They often had a biconcave form and always possessed curved margins.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor, Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

Gould's Medical Dictionary*

IF THERE is one book that every medical library and every physician *must* have, it is a medical dictionary. This new edition of Gould, long a favorite, will be found abreast of all the many and varied advances which have brought new and varied terms to medical literature. Numerous tables and new illustrations, many in color, make this new edition highly acceptable. It is highly recommended.

Textbook of Bacteriology†

THROUGH twelve editions Jordan's *Bacteriology* has established its own place. Dr. Burrows has taken the place of the late Dr. Jordan in editing the thirteenth edition. It has been somewhat enlarged and, with minor exceptions, completely rewritten. Chapters devoted to highly specialized fields, such as soil, industrial and dairy bacteriology, have been regrouped in a chapter on Bacterial Physiology. The relation of bacteria to disease is considered in its broad aspect. This applies especially in the section on virulence and resistance.

The editor has been conservative in his treatment of nomenclature and classification. He uses no single taxonomic scheme, although he favors most of the terms adopted in Bergey's *Manual*.

The new edition gives every promise of enjoying the popularity of its predecessors.

Foreign Bodies Left in the Abdomen‡

THIS is a summary review of the entire literature of the subject, analyzed and discussed with regard to methods of prevention and to legal responsibilities.

The first record of a sponge left in the abdomen was in 1895, when a sea sponge was discovered. Sea sponges evidently were used quite frequently in the early days. Very few appear in the literature after 1900, although one was found in 1916, which apparently had been introduced in the same year.

In 1901 a towel, measuring one foot by two feet, was left in an abdomen.

The interval between loss and recovery of sponges is sometimes very long. After the fifth year secondary operations caused by sponges are usually due to intestinal complications, although nearly half of them become encapsulated, cause little or no trouble, and are found only incidentally in other operations.

Methods of preventing loss are discussed in much detail. These include sponge counts, metal tracers, and the continuous sponge.

Most of the instruments left in the abdomen are forceps, hemostats, and needles, although one report from Germany described a pair of spectacles.

Drains are lost often enough to be important. Some foreign bodies in the abdominal cavity were originally swallowed.

The legal decisions reviewed in considerable detail will be of greatest interest to any who have been unfortunate enough to have left articles in the abdomen.

By Harry Sturgeon Crossen, M.D., School of Medicine, Washington University; [illegible] Crossen, *LL.B.*, School of Law, Washington University, St. Louis, Mo. [illegible] with 212 illustrations including 4 color plates. The C. V. Mosby Company, St. Louis, 1940.

Approved Laboratory Technic*

THE third edition of the *Approved Laboratory Technic* includes such new procedures as the quantitative determination of prothrombin, methods for semen examination, the determination of urobilinogen in the urine and feces, hippuric acid in the urine, serum lipase determination, the simplified Kolmer complement fixation test, the Eagle modification of the Wassermann, determination of vitamin C in urine and plasma, determination of sulfonamide compounds in the blood and urine, and determination of thiocyanates in the blood.

This book was originally prepared under the auspices of the American Society of Clinical Pathologists.

In addition to the authors, twenty-eight men have collaborated in the preparation of certain sections.

Science and Seizures†

A VERY readable popular book for the use of the patient with epilepsy or migraine, this work was written from the point of view of neuropsychiatry. The patient with epilepsy (Lennox prefers to call it seizures) will get a clearer understanding of his condition from perusal of this book and will be relieved of the feeling that he is stigmatized by his disease. For this purpose the book should be widely recommended.

Physicians, even neuropsychiatrists, will also enjoy it and, unless they have kept up with the most recent advances in the study of seizures, they will gain much from its perusal.

Dr. Lennox devotes considerable space to discussion of the importance and significance of electroencephalograms. Some workers in the field may feel that the generalizations concerning the significance of the electroencephalogram are somewhat premature, not as yet generally accepted. The deductions, however, are based upon fact as it is known today and certainly add to the interest of the volume.

Cardiac Classics‡

CARDIAC CLASSICS contains reprints and translations of fifty-two contributions by fifty-one men who have done most to advance our knowledge of cardiology. Aside from the fun that one derives from reading those essays which have made history in medicine, there is a utilitarian need for this type of volume for those who are writing today. Often quotations from earlier investigators are distorted successively by men who fail to go back to the original source for their quotations. The truth of this is so obvious to those who do much writing that examples need not be given. Often the misquotations actually change the entire sense of a remark.

Another realization came to the reviewer as he went through the pages of this excellent work: how few essays written by medical men deserve reprinting and rereading. How much print paper is wasted with rehash and unimportant stuff.

*Approved Laboratory Technic—Clinical Pathological, Bacteriological, Mycological, Parasitological, Serological, Biochemical and Histological. By John A. Kolmer, M.S., M.D., Dr. P.H., Sc.D., LL.D., L.H.D., F.A.C.P., Professor of Medicine, Temple University; Director of the Research Institute of Cutaneous Medicine, Philadelphia; formerly Professor of Pathology and Bacteriology, Graduate School of Medicine, University of Pennsylvania; and Fred Boerner, V.M.D., Assistant Professor of Bacteriology, School of Medicine and Graduate School of Medicine, University of Pennsylvania; Bacteriologist, Graduate Hospital, Philadelphia. Cloth, ed. 3, 921 pages, $8.00. D. Appleton-Century Company, New York and London, 1941.

†Science and Seizures: New Light on Epilepsy and Migraine. By William Gordon Lennox, M.D., Sc.D., Hon. Assistant Professor of Neurology, Harvard University Medical School; Visiting Neurologist, Boston City Hospital; President International League against Epilepsy; Vice President Laymen's League against Epilepsy; Secretary Harvard Epilepsy Commission. Cloth, 258 pages, with 10 illustrations, $2.00. Harper & Brothers, New York and London, 1941.

‡Cardiac Classics—A Collection of Classic Works on the Heart and Circulation With Comprehensive Biographic Accounts of the Authors. Fifty-Two Contributions by Fifty-One authors. By Fredrick A. Willius, M.D., M.S. in Med., Chief, Section of Cardiology, the Mayo Clinic; Professor of Medicine, the Mayo Foundation for Medical Education and Research, the Graduate School, the University of Minnesota; and Thomas E. Keys, A.B., M.A., Reference Librarian, the Mayo Clinic; formerly Carnegie Fellow, the Graduate Library School, the University of Chicago. Cloth, 858 pages, $10.00. The C. V. Mosby Company, St. Louis, 1941.

The work starts with William Harvey and ends with Herrick's description of coronary occlusion.

One is disappointed in not seeing an essay from the pen of Thomas Lewis, but it is interesting to observe that there are more index references to his name than to that of any other cardiologist outside the favored fifty-one.

Dynamics of Inflammation*

AN OUTSTANDING contribution to our knowledge of inflammation, this book differs from the older pathologic concept in the sense that it is dynamic rather than static. The author analyzes the physiology and pathological physiology of the migration of leucocytes from the capillaries and their activities in areas of infection and damage, and associated chemical changes as well as modifications in these activities brought about by immunity and allergy. This has been the field of Menkin's original investigations for many years. In addition he brings to the monograph a wealth of his own material.

Although the volume represents a tremendous amount of original investigations, Dr. Menkin's conclusions, his interpretations of the mechanism of inflammation, are such as are now widely accepted. The evidence presented in favor of acceptance of the new trophic substance which he has named leukotaxine is logical.

ITEM

Antipneumococcic Action of Cinchona Derivatives

Mellon Institute, Pittsburgh, Pa., is distributing gratis to all interested specialists who request them copies of a publication entitled "Structure and Antipneumococcic Activity in the Cinchona Series."

Erratum

The first paragraph on page 1458 of the August issue of the JOURNAL, in an article entitled "Studies on the Clinical Significance of the Serum Proteins" by Benjamin M. Kagan, M.D., Richmond, Va., should read:

"There are in existence several colorimetric methods which, while less difficult to use, do not approach the simplicity of usual routine tests, *and* some of which are subject to errors up to 10 per cent."

*Dynamics of Inflammation. An Inquiry Into the Mechanism of Infectious Processes. By Valy Menkin, Department of Pathology, Harvard University Medical School. Cloth, 244 pages, $4.50. The Macmillan Company, New York, 1940.

CLINICAL AND EXPERIMENTAL

EPINEPHRINE AND EPHEDRINE ANALOGUES AND THEIR CLINICAL ASSAY

WARREN T. VAUGHAN, M.D., ROLLIN M. PERKINS, M.D.,* AND VINCENT J. DERBES, M.D.,* RICHMOND, VA.

DISCOVERY of the chemical structure of epinephrine by Abel (1897) and its synthesis by Stolz (1904) and Dakin (1905) have been followed by the synthesis of many derivatives possessing pharmacologic actions resembling those of epinephrine.

The early synthesis of sympathomimetic amines by Barger and Dale, gave impetus to this study. They studied aliphatic amines with no attached benzene ring. Amines with less than four carbon atoms had little activity. Those with from four to six had some pharmacologic action. Addition of the benzene ring to a two-carbon chain, with two carbon atoms separating the ring from the nitrogen produced clear-cut sympathomimetic action (phenylethylamine, Table I). The introduction of hydroxyl groups at the para or meta positions within the ring resulted in more effective epinephrine-like action.

Epinephrine has hydroxyl groups in both meta and para positions. This arrangement in the ring constitutes the catechol nucleus. We may describe epinephrine as a compound formed by the union of the catechol nucleus with a two-carbon aliphatic amine in which hydroxyl is attached to the proximal carbon and a methyl radical to the nitrogen.

It was natural to assay those compounds which closely resembled epinephrine in terms of the latter as the standard. The most easily measured epinephrine effect is elevation of the blood pressure. In early pharmacologic studies, epinephrine derivatives were graded according to pressor activity and its duration, with pressor response to epinephrine designated as unity. Pressor action was found to be controlled in great measure by the hydroxyl groups in

*Upjohn Research Fellows.

Received for publication, May 1, 1942.

the benzene ring. Tyramine differs from phenylethylamine only in the presence of a para hydroxyl group. The pressor activity of the former is double that of the latter. The addition of another hydroxyl group again doubles the ability of the compound to increase blood pressure (Table I, *4*). It will be noted in the last column of Table I that, as pressor activity increases, its duration becomes shortened.

TABLE I

CHEMISTRY AND PHARMACOLOGY OF SOME ADRENALIN-LIKE COMPOUNDS	 CH—CH—NH					PRESSOR ACTIVITY (ADRENALIN-1)	PRESSOR DURATION (ADRENALIN-1)
1. Phenylethylamine (PE)	H	H	H	H	H	1/200-1/80	3-4
2. Tyramine	OH	H	H	H	H	1/100-1/20	2
3. p-methoxy-PE	OCH_3	H	H	H	H	1/300	4
4. Dihydroxy-PE	OH	OH	H	H	H	1/35	1
5. Epinine	OH	OH	H	H	CH_3	1/12	2
6. Arterenol	OH	OH	OH	H	H	3/2	2
7. Epinephrine	OH	OH	OH	H	CH_3	1	1
8. Neosynephrin	H	OH	OH	H	CH_3		
9. Paredrine	OH	H	H	CH_3	H		
10. Benzedrine (beta-phenylisopropylamine)	H	H	H	CH_3	H	1/300-1/100	5-10
11. Propadrine	H	H	OH	CH_3	H	1/300-1/60	7
12. Ephedrine	H	H	OH	CH_3	CH_3	1/300-1/100	7
13. Corbasil	OH	OH	OH	CH_3	H	1/4	2
	Para	Meta	Beta	Alpha			

The pharmacologic activity of epinephrine (at least as regards its pressor effect) appears dependent upon the catechol nucleus. The nucleus apparently accounts also for the short pressor duration since it is rapidly oxidized. Efforts have been made to counteract this rapid oxidation. Methylation of the hydroxyl radical increases stability but causes loss in pressor effectiveness (Table I, *3*).

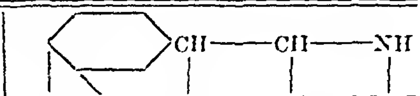
For better orientation we may review the prevailing hypotheses concerning the synthesis and destruction of epinephrine. There are gaps in the experimental evidence. The hypotheses cannot be considered proved, but for simplicity we shall present them didactically, because the theories are those most generally favored by chemists and pharmacologists and because they present a sequential picture, facilitating clinical discussion. Until there are better hypotheses, progress must be based on those now in favor.

Phenylalanine seems to be the precursor of epinephrine. It is an amino acid indispensable for growth. The possible succession of chemical changes brought about by enzymes is illustrated in Table II. The introduction of one hydroxyl in the benzene ring transforms phenylalanine into tyrosine, another amino acid. A second hydroxyl introduction produces dihydroxyphenylalanine. Next, the beta carbon is oxidized, after which the amino group is methylated. Decarboxylation of the alpha carbon produces epinephrine.

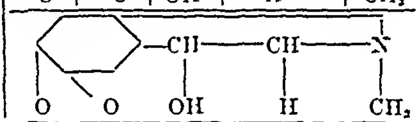
Destruction of epinephrine is an oxidative process, which can be brought about in two ways. In one, oxygen replaces the hydrogen of the hydroxyls in the catechol nucleus, producing an unstable quinone of epinephrine. Further internal oxidation reduction and molecular rearrangement result in an unstable indole derivative called adrenochrome, in which the nitrogen is attached to the benzene ring. Adrenochrome is inactive and appears responsible for the red brown discoloration of oxidized epinephrine.

This auto-oxidative process probably occurs in vitro. While it may occur in vivo, there appears to be a second process, incited by an enzyme, amine oxidase, which attacks many amines, converting them into aldehydes and ammonia (or in the case of epinephrine, into aldehydes and methylamine). Amine oxidase effect is comparable to that of cholinesterase against acetylcholine. Probably epinephrine is not destroyed too rapidly in the tissues because of the protective action of amino acids, which serve as hydrogen donors for epinephrine. Glutathione and ascorbic acid also serve as reducing substances. Both are abundant in the adrenal glands and probably participate in stabilization of epinephrine in the gland and in the blood leaving it.

TABLE II



SYNTHESIS AND OXIDATION OF EPINEPHRINE				CH	CH	NH
Synthesis	1. Phenylalanine	H	H	H	COOH	H
	2. Tyrosine	OH	H	H	COOH	H
	3. Dihydroxphenylalanine	OH	OH	H	COOH	H
	4. Oxidation of beta carbon	OH	OH	OH	COOH	H
	5. Methylation of amino group	OH	OH	OH	COOH	CH_3
	6. Decarboxylation	OH	OH	OH	H	CH_3
Oxidation	7. Quinone of epinephrine	O	O	OH	H	CH_3
	8. Adrenochrome	O	O	OH	H	CH_3



Briefly summarizing, the pressor activity of epinephrine and probably its other sympathomimetic effects are due primarily to the presence of hydroxyl groups in the benzene ring. This catechol nucleus also accounts for the evanescence of the response, epinephrine being rapidly oxidized by amine oxidase. The effectiveness of related synthetic compounds is also due to hydroxyl groups in the benzene ring.

Impetus was given the study of other synthetic compounds of potential clinical value by the identification of ephedrine (Table I). Ephedrine differs from epinephrine in the absence of hydroxyl groups in the benzene ring and the presence of a third carbon atom in the aliphatic chain in the form of a methyl group. Ephedrine effect is similar to that of epinephrine, but it does differ from it. Without the oxidizable catechol nucleus, ephedrine is not as easily broken down and is, therefore, effective when taken by mouth. For the same reason, its pressor activity is less, but the duration of pressor action is lengthened. Other physiologic effects, such as relief of bronchospasm, are similarly less pronounced.

Today there are over 200 compounds related to epinephrine and ephedrine which might have some sympathomimetic action. Of those related to ephedrine we shall use as illustrations only the four indicated in Table I. These illustrate the outstanding differences between the epinephrine group and the ephedrine group, summarized as follows:

In the absence of the catechol nucleus, the compounds are not destroyed as quickly.

The methyl group in the alpha carbon position prolongs pressor action but diminishes its intensity.

This methyl group may be responsible for the central nervous stimulation.

The addition of a phenolic hydroxyl group reduces the central stimulation. Paredrine has an arrangement in the benzene ring similar to that of tyramine, while its side chain is similar to benzedrine. It does not stimulate the nervous system. Corbasil is nonstimulating.

Ephedrine and related compounds, unlike epinephrine, produce tachyphylaxis. Successive doses given at short intervals exert progressively diminishing effect.

Gaddum's theory of the action of ephedrine, propadrine, benzedrine, and related compounds is an attractive hypothesis. Amine oxidase destroys epinephrine by oxidation. Ephedrine, like epinephrine, has an attraction toward amine oxidase. Indeed, its attraction is greater. Ephedrine combines with amine oxidase, thereby protecting the epinephrine normally present in the body. Consequently, epinephrine appears to become more active. Ephedrine potentiates epinephrine by blocking amine oxidase. Ephedrine being slowly oxidized, persists in combination with amine oxidase.

This would explain why small doses of ephedrine appear to increase the activity of epinephrine. Without having made quantitative studies, we have recognized the apparent increased effectiveness of an ephedrine-epinephrine combination as compared with straight epinephrine in clinical work and have used such a combination routinely for the past ten years. Our preparation consists of equal parts of 1:1,000 epinephrine solution and 3 per cent aqueous ephedrine. The dose of the combination has been the same as the dose of 1:1,000 epinephrine alone, usually 0.3 c.c. of the mixture.

Large doses of ephedrine sometimes appear to do the reverse, blocking epinephrine effect. The explanatory theory is that ephedrine, like epinephrine, may combine with the chemicals of the sympathetic myoneural junction. Ephedrine exerts no sympathomimetic action itself, and in this chemical combination it blocks epinephrine, obstructing the activity of the latter. With our small clinical doses this has not been a problem.

A suggested explanation of the central stimulation of benzedrine (Mann and Quastel, 1940) is based on the theory that these compounds combine with amine oxidase, blocking its activity. As stated above, the oxidation of certain amines releases aldehydes. Aldehydes exert an inhibiting effect on cerebral respiration (oxidation). Benzedrine binds amine oxidase so that it cannot oxidize the amines. Toxic aldehydes are not liberated. As a consequence cerebral respiration is less impeded.

CLINICAL APPLICATION

From time to time new synthetics of this series are proposed for clinical use. The first question usually is, "Is it as good as epinephrine or ephedrine?" The tendency is to weigh the effectiveness of any other compound in terms of these two. Propadrine, benzedrine, and neosynephrin are compared with ephedrine. Proprietary nebulizers with solutions having special trade names such as Vaponefrin or Neosol are presented, sometimes with the innuendo that the solution is superior to epinephrine. On questioning, one is usually informed

that the material is alpha methylamino-beta-hydroxyl dihydroxybenzene. Study of Table I indicates that this is epinephrine. For general sympathomimetic effect, nothing has as yet been found superior to epinephrine.

We do not imply that no such compound may eventually be found. Gunn has formulated four criteria for the ideal sympathomimetic: (1) it should be effective when given orally; (2) its action should be more prolonged than that of epinephrine; (3) it should be more certain than ephedrine; (4) there should be no central stimulation. The nearest approach in our past experience has been the mixture of epinephrine and ephedrine, which, however, still requires hypodermic administration.

Though the ideal sympathomimetic is not yet at hand, it may be that one compound is superior for one type of effect, while others are better for other actions. This is true with propadrine, benzedrine, neosynephrin, and paredrine. The question should not be "Are they as good as epinephrine or ephedrine," but rather, "Do they excel these in one or another activity, and do they have any superiority in lessened undesirable side effects?"

Epinephrine, for example, is effective in shrinking turgescent nasal mucosa. In fact, it is too effective, producing so much vasoconstriction with tissue anoxia that secondary vasodilatation may ensue, with consequent increased edema. One to 3 per cent ephedrine produces local decongestion, usually adequate, and not enough to cause anoxia. Neosynephrin appears to have special value here in that it is effective in much lower concentration (0.25 per cent). Although benzedrine produces undesirable central stimulation, its base is volatile. This gives it definite value as an inhalant in nasal allergy.

On the other hand, neosynephrin exerts little action when taken internally, except in large doses. It is about as effective as ephedrine in relaxing bronchospasm, but for adequate dosage it must be given hypodermically and is therefore inferior to ephedrine, although it has a slight superiority in that it exerts less nervous stimulation. Although benzedrine dilates the bronchi, this effect is not marked, and there is little change in respiratory rate, minute volume, or vital capacity. There is no unanimity of opinion concerning its action on gastrointestinal musculature.

We see therefore that neosynephrin and benzedrine base are superior compounds for topical application but possess no outstanding superiority with regard to other effects in the allergic diseases. The value of benzedrine in narcolepsy might be mentioned parenthetically, although this is not in the category of allergic diseases.

Paredrine exerts little action on the bronchi or gastrointestinal tract. It has pronounced pressor action and is not stimulating to the nervous system. Its outstanding effectiveness is as a mydriatic.

Propadrine exerts less central stimulation than ephedrine or benzedrine, has about the same pressor activity as ephedrine, and is about as effective when applied to the nasal mucosa. It may be given by mouth in the same dose or double the dose of ephedrine. Propadrine therefore finds use with patients who find ephedrine too stimulating.

Many other compounds have been studied, including kephrine, synephrin, arterenol, paredrinol, sympatol and epinine. Since none have superior effectiveness in relieving local or general allergic reactions, we shall not discuss them.

The list of compounds which might be superior in one or another respect is not complete, and the desirability of continuing the search is obvious, even though one must realize that a majority of the related compounds may be less effective than those now available.

PLAN OF INVESTIGATION

On the assumption that certain compounds may show superiority in relieving one or another but not necessarily all allergic responses, clinical investigation should include assay of sympathomimetic and allied responses in all tissues that lend themselves to objective investigation. Our preliminary program was outlined as follows:

Increased Capillary Permeability. A compound which will diminish capillary hyperpermeability, basically characteristic of the allergic response, should be of value, provided no undesired side effects accompany this action. Objective study might include the action of drugs upon experimentally induced histamine and allergen wheals. Epinephrine or ephedrine, or both, should be used as standards for comparison.

Localized subcutaneous edema of the angioneurotic type might be studied in its response to sympathomimetic drugs by determination of tissue tension in the edematous area (Vaughan and Pipes, 1940).

Both methods were employed, but it was found that tissue tension changes in wheals were not always sufficiently pronounced for reliable evaluation, and that the problem of producing angioneurotic edema at will in predisposed persons could not be easily solved. Tissue tension studies were therefore discontinued.

The action of compounds on whealing was studied in both normal and allergic persons.

Bronchial Obstruction. The obstructive phenomenon in bronchial asthma is probably due to local submucosal edema as well as bronchospasm. In the present study it is unimportant which is the dominant factor, since the desired therapeutic result, bronchial dilatation, would hold in either case.

Alexander and Kountz and others have shown that epinephrine and ephedrine increase vital capacity in asthmatic and in normal persons. Starr, also Richards, Barach and Cromwell suggest that maximum ventilation in liters per minute may be a better index of improved pulmonary function than vital capacity.

At the beginning, vital capacity studies were made. Later these were supplemented with ventilation capacity determinations.

Local Vasomotor Response. Here again it is unimportant whether the reaction in the nose is due to increased capillary permeability or vascular dilatation, or both. The therapeutic criterion is increased ventilation through the nose.

We have found the most satisfactory measure of nasal mucosal shrinkage in the Glatzel-Mulinos nasal mirror. This gives roughly quantitative results. Our adaptation of this method has been described elsewhere (Vaughan and Derbes, 1941).

Gastrointestinal Hypertonicity. There is no generally accepted objective method for clinically determining the response of smooth muscle in the intes-

tines. The methods used have yielded conflicting results (e.g., in the case of benzedrine). It seemed fruitless to repeat these procedures. Subjective tests were made with some persons subject to repeated gastrointestinal allergic reactions, manifested especially by distention. These patients tried different preparations repeatedly, not knowing which were being given, and expressed their conclusions as to which were more effective. We found propadrine and ephedrine most effective. Propadrine was preferred since it produced less jitters.

Toxic Allergic Fatigue. In our experience a phase of pronounced fatigue is an occasional accompaniment of food allergy, especially if the allergenic food is not rapidly removed by vomiting or diarrhea. This fatigue may appear within from thirty minutes to several hours, and usually lasts for twenty-four hours or longer. Certain persons appear to be especially susceptible to this response.

Here, again, any evaluation must be subjective. Two persons who were subject to allergic fatigue and were well acquainted with the manner of their response to allergenic foods evaluated different compounds in terms of comparable relief from 5 mg. of benzedrine. Benzedrine was most effective and had least unpleasant side effect in 5 mg. dosage. Propadrine hydrochloride, 25 mg., and neosynephrin hydrochloride, 10 mg. capsules, were somewhat less effective but had a definite benzedrine-like stimulating action and no unpleasant side effects. Beta-o-methoxyphenyl-n-propyl*di*methylamine hydrochloride,* 50 mg. capsules, was slightly lower in stimulating action than propadrine. Ephedrine caused little stimulation and much jitters.

It is regrettable that no adequate objective measures of therapeutic benzedrine effect are available. This drug in usual dosage produces no consistent or diagnostic change in metabolic rate, blood sugar level, or deep reflexes, or in the formed elements of the blood. Evaluation must be made in terms of elevation of mood, euphoria, lessened fatigue, enhanced motor and speech activity, feeling of increased efficiency and increased ability to concentrate, irritability and sleeplessness.

Undesired Effects. Notations were made of undesired responses, when present, such as palpitation, tremor, "jitteriness," blood pressure elevations, tachycardia, urinary retention, etc.

ORIENTATION STUDIES

A preliminary survey was made to determine whether the contemplated methods would be sufficiently sensitive. This evaluation included study of the blood pressure, pulse rate, and vital capacity and notation of the presence or absence of palpitation or jitters. Increase in the number of leucocytes and erythrocytes per cubic millimeter of blood was also determined (Table III).

We started with methyl racephedrine and beta-o-methoxyphenyl-n-propyl*di*methylamine hydrochloride† (Table IV). These were compared with epinephrine and ephedrine.

*This will hereafter be simplified to read, "methoxyphenyl-propyl*di*methylamine." The italicized -di- serves to differentiate this compound from a similar mono- compound which will be mentioned subsequently in this report.

†The analogues studied were prepared according to the methods described by Woodruff, Lambooy, and Burt.

Three tenths cubic centimeter of 1:1,000 epinephrine subcutaneously produced an average increase in blood pressure of 24 mm., an increase in pulse rate of 11, and an average increase in vital capacity of 272 c.c. This was usually accompanied by palpitation and jitters.

Ephedrine, 25 mg. subcutaneously, caused an average rise of 12 mm. blood pressure, an increase in pulse rate of 5, and an increased vital capacity of 167 c.c. This also usually caused jitters.

TABLE III

RESPONSE TO SUBCUTANEOUS EPINEPHRINE AND ANALOGUES	BLOOD PRESSURE INCREASE	PULSE RATE INCREASE	LEUCOCYTE INCREASE	ERYTHROCYTE INCREASE	AVERAGE INCREASE IN VITAL CAPACITY	PALPITATION AND JITTERS
Epinephrine 1:1,000 0.3 c.c.	24	11	2,600	150 M	272	Yes
Ephedrine 25 mg.	12	5	700	300 M	167	Yes
Methyl racephedrine 25 mg.	0	0	None	200 M	74	No
Beta-o-methoxyphenyl-n-propyldimethylamine hydrochloride 25 mg.	0	0	None	0	74	No

Methyl racephedrine and methoxyphenyl-propyl*di*methylamine caused no increase in blood pressure or pulse rate and no jitters. They did produce an increased vital capacity, less, however, than that produced by ephedrine (Table III). The second preparation caused a slight decrease in blood pressure.

These studies were made without knowledge of the previous laboratory results with animals. They were then compared. The correspondence between laboratory and clinical results appeared to be satisfactory. The pressor activity of ephedrine had been found to be from 1/100th to 1/250th that of epinephrine, while methyl racephedrine was 1/4,000th and methoxyphenyl-propyl*di*methylamine had been slightly depressor in animals. The correlation in bronchial relaxation was not as good. We found an average increase in vital capacity after methyl racephedrine of only 74 c.c.; and after methoxyphenyl-propyl*di*methylamine, 74 c.c. Isolated lung tests had indicated that the two new compounds, especially the latter, might be superior to ephedrine in relaxing bronchoconstriction. We had given them in the same dosage as ephedrine (25 mg. subcutaneously).

The preliminary studies indicate that in identical dosage neither of the substitutes is as effective as ephedrine in increasing vital capacity. Further, none of the three is as effective as epinephrine. However, two possibilities were obvious. First, the new drugs might be as effective as ephedrine, or more so, if given in larger doses. Toxicity studies indicate that much larger dosage may be safely employed (Table IV). If in larger quantities they do not produce jitters as does ephedrine, they might have value in therapy. The second possibility was based on the absence of pressor response and tachycardia. Some effective drug may be found which in adequate dosage causes no increase in blood pressure.

Five subjects were used in each vital capacity series, four normals and one asthmatic. Ephedrine produced increased vital capacity in all subjects.

Epinephrine failed to produce increase in one subject. and the two ephedrine analogues failed in two and three subjects, respectively.

The one asthmatic in the series had an increase of 400 c.c. after epinephrine. 70 c.c. after ephedrine, and none after methyl racephedrine or methoxyphenyl-propyl*di*methylamine.

The second phase of the orientation study involves disappearance of histamine wheals after medication. Wheals were produced by the injection of 0.03 c.c. of 1:1,000 histamine hydrochloride. They were fully evolved after five minutes. We first determined the time required for involution of this wheal. Thereafter, the drugs were injected subcutaneously five minutes after the intracutaneous injection of histamine.

No more rapid involution was caused by 47.1 mg. of racephedrine than in the controls, while 94.2 mg. of racephedrine caused as rapid involution as after 0.3 c.c. of 1:1,000 epinephrine. Subjective symptoms were as pronounced after 94 mg. of racephedrine as after epinephrine. Palpitation and jitters persisted for four hours. At the end of four hours another histamine wheal was produced. This wheal was smaller than the original, indicating an inhibiting effect from 94.2 mg. of racephedrine at the end of four hours.

We next compared the involution after 50 mg. of ephedrine with that after 46.4 mg. of methyl racephedrine and 45.8 mg. of methoxyphenyl-propyl*di*methylamine. Methyl racephedrine was less effective than ephedrine. The second product, in slightly lower milligram dosage, was comparable to ephedrine.

This observation, if substantiated by a larger series, might suggest a specific function of methoxyphenyl-propyl*di*methylamine in the control of allergic diseases associated with whealing or increased capillary permeability, especially since in comparable dosage (46 mg. vs. 50 mg.) less side effect (palpitation and jitters) was noted than after ephedrine.

The final phase of the orientation study consisted in therapeutic trial, giving the two preparations in capsule form to persons with active allergic symptoms.

Fifty-two patients with various allergic symptoms were given methyl racephedrine, 51 patients received methoxyphenyl-propyl*di*methylamine (each in 25 mg. dosage by mouth). Of these, 34 were given both. Not all reported results. Thirty-two reported on the former, 35 on the latter, and 22 on both.

Of the 32 receiving methyl racephedrine, 19 reported subjective improvement and 2 described unpleasant symptoms. Of the 35 receiving methoxyphenyl-propyl*di*methylamine, 25 were helped and 2 reported unpleasant symptoms.

Eleven reported equal relief from both drugs, seven had no relief from either, three concluded that methyl racephedrine was more effective. five that methoxyphenyl-propyl*di*methylamine was more effective, and 14 concluded that the drugs were equally beneficial (Table V). The drugs were equally efficacious in asthma and rhinitis. Methoxyphenyl-propyl*di*methylamine was possibly more effective in urticaria.

These patient experiences appeared to confirm the objective studies in indicating that the drugs had some effectiveness in relieving bronchospasm and that the second was more effective in the relief of whealing.

TABLE IV

CHEMISTRY OF COMPOUNDS STUDIED							ACUTE TOXICITIES (MG. PER KG.)				CHRONIC TOXICITIES (MG. PER KG.)			
											ORAL IN RATS		ORAL IN RABBITS	
							INTRAVENOUS IN RATS	INTRAVENOUS IN RABBITS	ORAL IN RATS	ORAL IN RABBITS	DOSE	MORTALITY	DOSE	MORTALITY
Ephedrine	H	H	OH	CH_3	CH_3	H	110	70	400	1,100	250 100	50% 0	100	0
Methyl racephedrine	H	H	OH	CH_3	CH_3	CH_3	90			1,100	250	0	100	0
Beta-o-methoxyphenyl-n-propyldimethylamine hydrochloride	H	OCH_3	CH_3	H	CH_3	CH_3	40			500	250	0	100	0

At the termination of these orientation studies, we believed that we had evolved a reliable technique for clinical pharmacologic study with which to study these and other ephedrine-like drugs in varying dosage using larger series of subjects.

Drug 2 = Beta-o-methoxyphenyl-n-propyldimethylamine hydrochloride.

ASSAY OF EPINEPHRINE AND EPHEDRINE ANALOGUES

The program of clinical assay as we have developed it includes determination of the pulse rate, blood pressure, and vital capacity before and after hypodermic administration of the test drug, and the effect of the injected material on the evolution or involution of histamine wheals produced either by iontophoresis or intracutaneous injections. In this series we did not study the local effect on the nasal mucosa.

In some of the series vital capacity determinations were supplemented by determinations of the coefficient of ventilation, as described by Brice. The coefficient of ventilation represents the ratio of oxygen consumed per minute to the oxygen respired for a minute. Theoretically, this test has an advantage over the vital capacity test, since, in the former, the patient rests passively, while in the latter active cooperation is required. Determination of the coefficient of ventilation is as follows:

The patient reports in at the same time each day, but not necessarily in the postabsorptive state. After a twenty-minute rest in bed a tracing is made

similar to that for the basal metabolic rate determination. We used the Jones metabolism apparatus. The usual line touching the points of expiration is drawn, as well as a line touching the points of inspiration. The distance between the lines measures the mean respiratory amplitude (MRA) or tidal ventilation. The time required to consume one liter of oxygen is determined, and from this the cubic centimeters of oxygen consumed per minute (O_2C) is calculated. The average respiratory rate (ARR) is obtained by counting the total respirations and dividing this total by the time required for the test. The coefficient of ventilation is then calculated from the formula:

$$CV = \frac{O_2C \times 100}{ARR \times MRA}$$

After completion of the tracing and recording of pulse rate and blood pressure, the patient stands next to the bed and blows into a spirometer for measurement of the vital capacity, after which he again lies down. These determinations are repeated after twenty minutes, after which the drug to be tested is injected subcutaneously. The four determinations, pulse rate, blood pressure, coefficient of ventilation, and vital capacity, are then repeated at twenty-minute intervals for an additional two hours and twenty minutes. The total time required is three hours. To avoid the possibility of cumulative effect, only one drug is tested each day. Each subject was tested with each of the drugs under study.

The response to 0.4 c.c. of 1:1,000 epinephrine as a standard for comparison was studied in nine cases. In seven, determinations were made of response to 50 mg. of ephedrine, 25 mg. of ephedrine, 50 mg. of methyl racephedrine hydrochloride, 50 mg. of beta-o-methoxyphenyl-n-propyl-*di*methylamine hydrochloride, and 50 mg. of beta-o-methoxyphenyl-n-propyl-methylamine hydrochloride.* The time required was not inconsiderable, amounting to 44 seances of three hours each. The results are summarized in Table VI B, which is derived as follows:

The actual determinations are averaged, as illustrated for the case of epinephrine in Table VI A. The first vertical column on Table VI B is derived from Table VI A by subtracting the higher of the two control figures from the highest of the several average figures recorded after the injection of epinephrine. Figures for the other drugs were derived from tables similar to Table VI A.

Epinephrine increased the vital capacity an average of 460 c.c. as compared with 120 c.c. for ephedrine, and 20, 70, and 30 c.c. each for the analogues tested. The coefficient of ventilation was increased most after epinephrine, while the analogues compared favorably with ephedrine in this respect.

As a check on the reliability of these objective methods of study of respiratory efficiency, clinical trial was made by dispensing 25 mg. capsules of the analogues to 70 patients with asthma, 35 with rhinitis, and 19 with urticaria for comparison with each other and with 25 mg. dosages of ephedrine. In no case was the effectiveness superior to that of ephedrine, and in the majority all three analogues were less effective. In comparing the three among themselves some patients believed that one was a little better, while other patients

See footnote, page 261.

selected another. While there was no uniformity beta-o-methoxyphenyl-n-propyl-*di*methylamine hydrochloride was selected a little more often as better than the other two in both asthma and urticaria. Furthermore, it depressed experimental histamine whealing definitely better than the other two, and indeed, slightly more effectively than did ephedrine in the same dosage.

It is our impression that the increase in vital capacity after these several drugs more nearly paralleled their actual effectiveness in relieving asthma than did the change in the coefficient of ventilation. This is fortunate to the extent that vital capacity determination is much less time-consuming than ventilation coefficient determination.

TABLE VI A

EFFECT OF SUBCUTANEOUS ADMINISTRATION OF 0.4 C.C. OF EPINEPHRINE ON THE PULSE RATE, BLOOD PRESSURE, VITAL CAPACITY, AND COEFFICIENT OF VENTILATION (AVERAGE OF 9 CASES)

	CONTROL		MINUTES AFTER INJECTION OF EPINEPHRINE						
	1	2	20	40	60	80	100	120	140
Pulse rate	81.3	81.3	81.4	81.0	81.1	79.4	78.9	78.0	80.0
Blood pressure	118.8	120.1	128.0	125.8	125.8	122.0	117.6	119.9	120.9
Vital capacity	2.49	2.60	2.99	3.06	3.0	3.01	2.74	2.63	2.66
Coefficient of ventilation	2.42	2.58	3.46	3.39	3.43	3.96	3.98	4.20	4.48

TABLE VI B

AVERAGE INCREASE IN PULSE RATE, BLOOD PRESSURE (MM. HG), VITAL CAPACITY (LITERS) AND COEFFICIENT OF VENTILATION AFTER SUBCUTANEOUS TREATMENT WITH TEST DRUGS

	EPINEPHRINE 1:1,000 0.4 C.C.	EPHEDRINE 50 MG.	EPHEDRINE 25 MG.	METHYL RACEPHEDRINE 50 MG.	BETA-O-METHOXYPHENYL-N-PROPYL-*di*-METHYLAMINE 50 MG.	BETA-O-METHOXYPHENYL-N-PROPYL-METHYLAMINE 50 MG.
Pulse rate	0.6	3	1.1	0.1	0.3	1.2
Blood pressure	7.9	10.5	3.2	11.3	5.6	11.9
Vital capacity	0.46	0.12	0	0.02	0.07	0.03
Coefficient of ventilation	1.90	0.41	0.87	0.92	0.76	0.69

As a final check we ran another series of vital capacity determinations on an additional six cases, comparing the response to ephedrine, methyl racephedrine, and beta-o-methoxyphenyl-n-propyl-*di*methylamine hydrochloride, given subcutaneously. Beta-o-methoxyphenyl-n-propylmethylamine hydrochloride was not used in this series, since it had been found clinically to be the least effective of the three. The average increase after ephedrine was 190 c.c.; after methyl racephedrine, 120 c.c.; and after beta-o-methoxyphenyl-n-propyl*di*methylamine hydrochloride it was 250 c.c. This shows the same superiority of the last over methyl racephedrine. When this last series is compared with the results in Table VI B there is a consistency in the findings, indicating that vital capacity determination is an adequate measure of the effectiveness of these drugs in asthma.

Beta-o-methoxyphenyl-n-propyl-*di*methylamine hydrochloride was no more effective clinically than ephedrine, and yet in the last series it was more effective in increasing the vital capacity to the extent of 60 c.c. We conclude that a difference of at least 60 c.c., probably better 75 or 100 c.c. must be present to be significant.

CONCLUSIONS

A program has been devised for the clinical assay of ephedrine analogues. This consists in serial determinations (before and after hypodermic administration of the drug) of pulse rate, blood pressure, and vital capacity; determination of the drug's effect on the evolution and involution of histamine wheals; and study of the local reaction in one side of the nose compared with the other side as a control, with the use of the Glatzel-Mulinos Mirror, as modified by Vaughan and Derbes.

Both epinephrine and ephedrine should be used as comparison controls. Superiority over ephedrine should require an average increase of vital capacity of at least 75 c.c. better than ephedrine.

Results of such objective study should be checked by clinical trial.

Failure of an ephedrine or epinephrine analogue to benefit one allergic symptom or reaction does not necessarily mean that it will be ineffective in all such reactions. Clinical assay should, therefore, evaluate the several types *of response.*

The drugs studied were provided through the courtesy of The Upjohn Research Laboratories where preliminary pharmacologic laboratory investigations had been made.

THE EFFECT OF TESTOSTERONE PROPIONATE IN THE TREATMENT OF ARTERIOSCLEROSIS OBLITERANS*

HERMAN ZURROW, M.D., GAMLIEL SALAND,† M.D., CHARLES KLEIN, M.D., AND STANLEY GOLDMAN, M.D., NEW YORK, N. Y.

THE effects of testosterone on the vascularity of the skin[1] and on muscle tissue metabolism[2, 3] have suggested its use in the treatment of patients with arteriosclerosis obliterans. This is a report of a preliminary study made with the intention of evaluating results in a small series of cases to determine the advisability of further work along these lines.

We studied 23 patients; eight of these were treated with biweekly intramuscular injections of 25 mg. of testosterone propionate; fifteen patients were control cases, receiving biweekly intramuscular injections of 3 c.c. of normal saline. All patients were ambulatory and had had a complete general and peripheral vascular study. The peripheral vascular status was determined on the basis of that study.[4] The patients had received no previous treatment for peripheral vascular disease. All were instructed as to foot hygiene and care, diet, and general measures, as outlined in our clinic routine. All patients were re-examined and studied at approximately three- to six-month intervals, and their peripheral vascular status was determined according to the following criteria:

A. Vascular anatomic status: This was determined by the evaluation of the amplitude of vessel pulsation determined by palpation, oscillometry, temperature changes, rubor on dependency and pallor on elevation, and roentgenograms for arterial calcification. This factor was graded from four plus (severe) to zero (no involvement).

B. Tissue anatomic status: This was determined by the degree of involvement of the superficial and deep tissues, and graded four plus when gangrene was present, three plus when ulceration was present, two plus when infection without gangrene was present, one plus when skin atrophy muscle atrophy, nail changes, or epidermatophytosis were present, and zero when no apparent involvement was present.

C. Rest pain: This refers to pain, other than that of claudication, and includes neuritic pain, paresthesias, coldness, night cramps. This was graded four plus for severe pain, to zero for no pain.

D. Claudication: This was measured by the patient's statement regarding the number of blocks he could walk before pain in calves supervened. He was graded four plus if he could walk only one-half block; three plus if he could

*From the Department of Peripheral Vascular Diseases, the Bronx Hospital, New York City.

Received for publication, June 26, 1942.

†Deceased.

walk one-half to two blocks; two plus, if two to four blocks; one plus, if more than four blocks, but still limited; zero, if no claudication was present.

E. Vascular reserve or capacity for vasodilatation: This was studied by means of the thermal vasodilatation test.[5] Where this test did not produce complete vasodilatation, nerve block was performed for corroboration.[6] Vascular reserve was graded four plus for full dilatation; i.e., a rise in skin surface temperature of the big toe to 30.5° C.; three plus, a 75 per cent rise from the initial temperature to 30.5° C.; two plus, a 50 per cent rise; one plus, a 25 per cent rise; zero, no rise.

F. Functional classification: This represents a summation of the disease factors. Class I, patients with organic vascular disease without symptoms; Class IIa, patients with organic vascular disease with minimal symptoms; Class IIb, patients with organic vascular disease with moderately severe symptoms; Class III, patients with organic vascular disease bedridden because of gangrene, infection, or intractable pain; Class IV, patients with symptoms, but with no demonstrable organic vascular disease.

We are reporting the results of our findings at the end of a three- to seven-month period, an eight- to fourteen-month period, and a fourteen- to eighteen-month period of treatment.

RESULTS

After treatment for three to seven months, four patients treated with testosterone propionate showed no improvement in vascular status; two of these patients were improved in tissue anatomic status, rest pain was lessened in two cases, claudication was improved in two cases, vascular reserve was improved in two cases, and functional status was improved in two cases.

Of the seven control cases observed for this period, four cases were improved in vascular anatomic status; two cases were improved in tissue anatomic status, rest pain; and claudication time were not improved in any case; three cases were improved in vascular reserve; two cases were improved in functional status.

It will be noted that for this period of study results were equivocal.

After eight to fourteen months of treatment with testosterone propionate, none of the six cases studied showed improvement in vascular anatomic status, two were improved in tissue anatomic status, rest pain was unrelieved in any case, four were improved in claudication time, three were improved in vascular reserve, and four were improved in functional status.

Of six control cases, two improved in vascular anatomic status, none improved in tissue anatomic status, none was relieved of rest pain, two were improved in claudication time, three were improved in vascular reserve, and two were improved in functional status.

It will be noted that, for this period, no encouraging results were obtained.

After fourteen to eighteen months of treatment with testosterone propionate, one of the two cases studied was improved in vascular anatomic status, one improved in tissue anatomic status, one in claudication time; rest pain was not present, both improved in vascular reserve, and one improved in functional status.

Of the six control cases, two improved in vascular anatomic status, two improved in tissue anatomic status, none were relieved of rest pain, three were improved in claudication time, in vascular reserve, and in functional status.

It will be noted that, for this period of treatment, results were not encouraging.

SUMMARY

Twenty-three patients suffering from obliterative vascular disease of the lower extremities were studied to note the effect of testosterone propionate on the signs and symptoms of their disease. Eight cases received biweekly intramuscular injections of 25 mg. of testosterone propionate; fifteen patients were observed as controls. The entire study was carried on over a period of eighteen months.

No significant effect was noted in the treated cases with respect to vascular anatomic status, tissue anatomic status, vascular reserve, claudication, rest pain, or functional status, as compared with the control cases.

A STUDY OF NORMAL CARDIAC RESPONSE TO WATER BELOW BODY TEMPERATURE WITH SPECIAL REFERENCE TO A SUBMERSION SYNDROME*

W. W. Tuttle, Ph.D., and Joyce L. Templin, M.A.
Iowa City, Iowa

In many institutions the importance of being able to swim as a means of self-preservation is felt so keenly that everyone is required to acquire an elementary mastery of it. Wherever large groups are required to go into a swimming pool, there are always some who experience reactions so disturbing that they never have a feeling of well-being when submerged† in water. In fact, in some cases, their reactions to submersion are so pronounced that it may appear hazardous to compel them to undertake to learn to swim.

These special cases always place an instructor in a quandary as to what to do. It is always a question whether the person who appears distressed when

*From the Department of Physiology, University of Iowa.

†Submersion as used here does not necessarily mean that a person is completely under water. In all cases the head is out of the water.

submerged in water merely is afraid, or whether he actually has physiologic reactions which might be hazardous were he left unsupervised while attempting to swim.

Each year there are numerous drownings attributed to heart failure, cramps, and exhaustion. Horton and Gabrielson[1] investigated the actual causes and concluded that in all probability many drownings were due, in reality, to a syndrome which they called "hypersensitiveness to cold." As a result of their investigations, they propose two tests which seem adequate for detecting persons who are hypersensitive to cold. By making use of such tests it is proposed that persons who are hypersensitive to cold may be appraised of the fact and can thus avoid unpleasant experiences due to submersion in cold water.

The tests proposed by Horton and Gabrielson are (1) the ice-cube test, and (2) the cardiovascular test. The ice-cube test is the simpler of the two but is less reliable because the systemic reactions are limited. It is done as follows: a cube of ice is held in contact with the forearm of a person in the sitting position for three minutes. If he is hypersensitive *to cold*, a wheal slightly *raised* and surrounded by *a red flare* will *appear* within two to five minutes after the removal of the ice cube.

The cardiovascular test is more complicated, but recommended, because it gives better systemic reactions. The test consists of establishing resting heart rates and blood pressures in the supine position. Then the hand and forearm of the subject are immersed in water at a temperature of 8° to 10° C. for from five to ten minutes. At the end of five minutes of immersion blood pressure and pulse rate are recorded. Then the subject's hand is removed from the bath, and blood pressure and pulse rate are taken every two minutes for the next fifteen to twenty minutes. At the same time observations are made for swelling, hives, color changes, and subjective sensations.

In hypersensitive persons exposure of the hand and forearm to a cold bath causes a definite decrease both in systolic and diastolic blood pressures, accompanied by an increase in pulse rate. Other symptoms of hypersensitiveness are swelling of the submerged hand and a definite mark of demarcation at the water line.

The reactions of hypersensitive people to cold are said to be due to a release of a chemical substance, histamine, from the tissue cells of the body in sufficient concentration to produce histamine reactions. In fact, the reactions of the hypersensitive person can readily be duplicated by the injection of histamine.

A number of studies have been reported on the effects of submersion in water on the physiologic reactions both of diving and land animals.[2] The results of these investigations parallel, to a considerable extent, those obtained in the case of man. When diving animals go from land into the water, they suffer a marked drop in heart rate, provided they are accustomed to the surrounding environment. However, when land animals are forcibly submerged, they do not show a similar reaction. The diving animals are observed to relax in the water, while the land animals fail to do so. Due to the unnatural environment even animals show physiologic, as well as psychologic, behavior which is dangerous to their existence in water.

The reactions of some animals, as well as some human beings, to even partial submersion in water raise the question: Should people be forced promiscuously into swimming pools, even though it is granted that swimming is a fine sport, a healthy exercise, and a useful thing to be able to do?

Researches dealing with water submersion show conclusively that man, when even partially submerged, experiences alterations in physiologic responses, especially those involving the cardiovascular system.

Wells[3] studied the effect of submersion in water of varying temperatures on heart rate. His technique was to place the subject in a supine position in a specially arranged tub in which water temperature could be controlled. He began with a temperature of 65° F. and gradually raised it to 110° F. The heart rate was counted at every 5 degree change in temperature. The results of this study are shown in Table I.

TABLE I

EFFECT OF SUBMERSION IN WATER OF VARYING TEMPERATURES ON THE HEART RATE OF 46 NORMAL MALE SUBJECTS

WATER TEMPERATURE DEGREES F.	HEART RATE PER MINUTE
65	72
70	61
75	68
80	66
85	65
90	64
95	64
100	70
105	87
110	120

The data in Table I show that there is a decrease in heart rate due to submersion until the water temperature approximates the body temperature. From this point on, there is an increase in heart rate as long as there is an increase in the water temperature. Since the temperature of swimming pools is maintained somewhere between 65° and 85° F., it is reasonable to expect that persons who respond normally will show a decrease in heart rate when submerged in a swimming pool.

The results of an experiment by Tuttle and Corleaux[4] are further evidence that the normal reaction to submersion in water is a significant decrease in heart rate. They compared the heart rates of 100 men sitting and standing in their normal environment with their pulse rates sitting and standing when submerged in water. The results of this experiment are shown in Table II. The figures are group means. The rates are for one minute.

TABLE II

MEAN PULSE RATES OF A GROUP OF 100 MEN BEFORE AND DURING SUBMERSION IN WATER OF SWIMMING POOL TEMPERATURE

	MEAN NORMAL PULSE RATE	MEAN PULSE RATE IN POOL	MEAN CHANGE IN PULSE RATE
Sitting	87	76	-11
Standing	98	84	-14

The data in Table II are further evidence that the normal reaction to submersion in water of swimming pool temperature is a decrease in pulse rate.

In seeking to establish the response of normal persons to submersion in water, it has been our experience that there has always been a small percentage of cases who failed to conform to the reactions of the group as a whole. It is the purpose of this investigation to study the reactions of this group who appear to react abnormally to submersion.

In order to have available nonconformants for further study a group of persons, unskilled in swimming, were examined in the class situation. Sixty-eight college women registered in beginning swimming classes at the University of Iowa served as subjects. Their ages ranged from 17 to 25 years.

Early in the instructional period each girl was tested as to the response of her heart to submersion. First, a resting pulse rate in the standing position was recorded. Following this, she climbed into the swimming pool and waded into water of shoulder depth. After three minutes her resting pulse rate was recorded again. The count was continued at two-minute intervals as long as there was a change in pulse rate, or until a constant rate was established.

Of the group of 68 women, 7 failed to show a decrease in heart rate while submerged in water and 61 responded normally. A summary of the data collected from the normal group is shown in Table III. The figures are group means per minute.

TABLE III

CARDIAC RESPONSE OF 61 NORMAL SUBJECTS TO SUBMERSION IN WATER

MEAN RESTING RATE STANDING (PER MINUTE)	MEAN RESTING RATE STANDING—SUBMERGED (PER MINUTE)	DIFFERENCE
90	77	-13

The data in Table III show that, on the average, there was a decrease of 13 beats per minute, which is practically the same as that reported for men. The mean decrease amounts to 14 per cent for women as compared to 12 per cent for men.

Table IV shows the relationship between resting pulse rate and the decrease caused by submersion.

TABLE IV

RELATION OF RESTING PULSE RATE TO THE DECREASE IN RATE CAUSED BY SUBMERSION IN WATER

RESTING PULSE RATE (PER MINUTE)	DROP DUE TO SUBMERSION
70-79	5
80-89	11
90-99	14
100-109	16

The data show that the extent of the decrease in pulse rate due to submersion in water varies directly with the resting pulse rate.

The group of 7 girls who failed to respond normally to submersion in water were studied further. There were two possible explanations for the abnormal response of this group: (1) there was lack of psychologic adjustment; that is, they were afraid. In the case of adjustment to submersion in water, fright alone is sufficient to account for a failure to adjust normally; that is, experience a fall in heart rate. (2) There was lack of physiologic adjustment,

Ordinarily, one can expect that repetition of exposure to a strange environment will condition a person so that he will exhibit normal behavior. On the other hand, it is reasonable to suppose that if abnormal response is due to the failure of some physiologic mechanism to adjust itself, repetition will fail to cause an appreciable alteration in the response.

The submersion experiment was repeated on the 7 subjects who failed to experience a decrease in heart rate during submersion. In the interim between the first test and the retest, each member of this group had participated in six or more class hours of swimming instruction, during which they were submerged in water. One would expect this amount of repetition to condition a person to the new environment. The results of the retest are shown in Table V.

Table V

Results of a Retest of Subjects Who Failed to Show Normal Reactions to Submersion in Water

Subject No.		Resting Pulse Rate (per minute)	Pulse Rate While Submerged (per minute)	Difference
18	First test	82	80	- 2
	Retest	86	74	-12
32	First test	92	90	- 2
	Retest	96	90	- 6
53	First test	78	78	0
	Retest	80	76	- 6
23	First test	68	82	+14
	Retest	72	76	+ 4
28	First test	80	80	0
	Retest	72	72	0
43	First test	86	90	+ 4
	Retest	82	92	+10
56	First test	86	88	+ 2
	Retest	88	88	0

The data in Table V show that 3 of the 7 subjects originally classed as abnormal became conditioned to submersion. Subject 18 behaved as a psychologic case, and after sufficient exposure to a water environment responded normally. Subjects 32 and 53 became conditioned to the water to such an extent that there was a significant fall in pulse rate due to submersion.

However, 4 of the 7 cases (23, 28, 43, and 56, Table V) failed completely to become conditioned. They never experienced a decrease in heart rate due to submersion, and it was suspected that they were failing to make normal physiologic adjustments to submersion.

Although the water in the swimming pool was at a temperature between 75° and 85° F. and could not be considered cold, it was decided to subject the nonconditioned group to a test for hypersensitiveness to cold. The cardiovascular function test was given to each, and all of them were hypersensitive to cold according to the criteria suggested by Horton and Gabrielson.

Although it would seem that this group of persons had been exposed to submersion a sufficient number of times so that they should be psychologically conditioned to it, it was decided to gather additional data relative to this point.

For this purpose, each of the subjects (23, 28, 43, and 56) was given a bathtub test. The procedure was to place each person in a bathtub in a sitting position and determine the resting heart rate. Then she sat at the side of the tub while it was filled with water of the temperature of that of the swimming pool. She returned to the tub and after three minutes of submersion the resting pulse rate was taken again. Under these conditions the resting pulse rate was established as previously described while the subject was submerged. The data obtained are shown in Table VI.

TABLE VI

EFFECT ON HEART RATE OF SUBJECTS BEING SUBMERGED IN WATER IN A BATHTUB

SUBJECT NO.	RESTING PULSE RATE (PER MINUTE)	PULSE RATE SUBMERGED (PER MINUTE)	DIFFERENCE
23	66	68	+2
28	68	70	+2
43	66	66	0
56	64	64	0

The data in Table VI show results similar to those obtained in the previous experiments. The data show that, although these subjects did not experience as great an increase in heart rate when submerged in the tub as in the pool, they failed to show any tendency toward a decrease. This lack of physiologic adjustment on the part of some persons may account for their being uncomfortable in the swimming pool, and also the difficulty experienced by them in learning to swim.

CONCLUSIONS

On the basis of data collected from 68 college women, the following conclusions are drawn concerning the effects of submersion in water:

1. Submersion in water of swimming pool temperature causes a drop in the heart rate of normally adjusted persons.
2. The amount of the decrease in heart rate due to submersion varies directly with the resting heart rate.
3. Failure to experience a decrease in heart rate when submerged in water below body temperature is due either to a lack of emotional adjustment (fear) or to a failure to compensate physiologically.
4. Where emotional factors are controlled, failure to experience a significant drop in pulse rate during submersion in water below body temperature indicates sensitivity to the water.
5. It is suggested that the conditions causing a failure to make normal adjustments to submersion in water be called the "submersion syndrome."

ETIOLOGY AND SERUM TREATMENT OF PERSISTENT EPIDEMIC AND POSTOPERATIVE HICCUP*

EDWARD C. ROSENOW, M.D., ROCHESTER, MINN.

PREVIOUS reports have been made[6, 7, 9, 11] on the consistent isolation from atria of infection of patients suffering from epidemic hiccup, of alpha or green-producing streptococci with which spasms of the diaphragm and other muscles (myoclonic encephalitis) have been produced experimentally in animals. Paroxysms of spasms of the diaphragm, sometimes associated with audible hiccup, were reproduced consistently by direct injection of suspensions of nasopharyngeal swabbings and filtrates of these and with pure cultures of the living streptococcus freshly isolated in dextrose-brain broth, as well as with the corresponding washed, heat and formalin-killed organisms and with filtrates of active cultures.[8] Characteristic symptoms developed in from twenty-four to seventy-two hours after inoculation of relatively small numbers of the living streptococci, in from four to twelve hours after inoculation of large numbers of the killed organisms, and in two to five hours after inoculation of Berkefeld N filtrates. The symptoms after inoculation of the living streptococci lasted the longest and often progressed to death in forty-eight to ninety-six hours; those that occurred after inoculation of the dead streptococci lasted usually from six to twenty-four hours, and those following inoculation of filtrates lasted two to six hours and then disappeared.

Cultural characteristics, virulence, cataphoretic velocity, and antigenicity of the streptococci resembled those of streptococci isolated in studies of epidemic encephalitis. Vaccines prepared from the spasm-producing streptococci protected rabbits against living cultures, the dead organisms, and active filtrates.[8] The streptococci were agglutinated specifically by the encephalitis antistreptococcic serum. This antiserum was found to neutralize specifically the "toxin" or poison produced by the streptococcus of persistent hiccup and to have striking curative effects, under controlled conditions, in animals in which spasms of the diaphragm were produced experimentally.[8] Moreover, the encephalitis antistreptococcic serum appeared curative in the treatment of patients suffering from epidemic and postoperative hiccup.[5, 9]

The occurrence of encephalitis and hiccup simultaneously or in sequence and the experimental production of lesions in animals, corresponding to those responsible for characteristic symptoms in patients, with the respective streptococci freshly isolated from atria of infection of patients having diverse manifestations during a changing epidemic from hiccup to neuromyeloencephalitis,[10] indicate that the inciting agent of these diseases is similar.[1-3, 10] Moreover, the

*From the Division of Experimental Bacteriology, the Mayo Foundation, the Mayo Clinic, Rochester.

Received for publication, June 29, 1942.

changes in localizing power of the streptococci, as isolated from persons, and in this study also from milk and air, on artificial cultivation and on repeated passage through animals indicate that the changes in type of disease in this and other outbreaks studied were due to acquired specificities of streptococci normally present in atria of infection of well persons and in nature generally in nonepidemic times.

The study of the problem of epidemiologic characteristics, causation, and serum treatment of persistent epidemic hiccup has been extended to that of persistent postoperative hiccup. In this new series of cases, as in those previously reported, the cases studied culturally, and those in which serum was used in treatment, occurred chiefly among patients of the Mayo Clinic. The historical aspects of this strange disease, its classification, its reproduction in animals, and its results of serum treatment in a previous series of cases have been set forth by C. W. Mayo. I am indebted to members of the staff and to physicians in widely separated regions of the United States for their cooperation in permitting me to study cases and for reports of results from the use of the serum in cases of intractable hiccup.

METHODS

A diagnostic cutaneous test[4] was made by injecting intradermally on the forearm of the patient 0.03 c.c. of a 10 per cent solution of the euglobulin fraction of antiserum prepared with the streptococci isolated in studies of encephalitis and, as controls, the englobulin of other antisera. The size of the maximal flare of erythema, which occurred in from five to ten minutes, was outlined with pen and ink and from this the area of erythema in square centimeters was determined.

Precipitation tests[4] were made with the whole encephalitis and other antistreptococcic sera and cleared extracts of nasopharyngeal swabbings and the serum of patients, and agglutination tests[4] were made with the respective antisera and convalescent sera and the streptococci as isolated and after passage through animals. Dilutions of 1:10, 1:50, 1:250. and 1:1,250 of the respective antistreptococcic sera, and dilutions of 1:20, 1:40, 1:80, and 1:160 of convalescent and control human sera were used in agglutination tests. Mixtures of respective diluted sera and suspensions of streptococci that had been grown in dextrose-brain broth and preserved in dense suspension in glycerin (2 parts) and 25 per cent solution of sodium chloride (1 part) were incubated at 50° C. for eighteen to twenty-four hours when readings were made, instead of incubating at 37° C. for one and a half hours and then placing in the refrigerator overnight.

Material for cultures and inoculation of animals was obtained chiefly from swabbings of nasopharynges, from pus expressed from tonsils or aspirated from pyorrhea pockets, from urine, from pus expressed from prostates, from samples of stool, and in postoperative cases, in addition, from localized infections, if present, such as appendiceal abscess and infected gall bladder. Cultures were made on blood agar plates and in dextrose-brain broth.

Routinely two rabbits, in special instances as many as ten rabbits per case, and in some instances guinea pigs, were inoculated intracerebrally with 0.1 and

0.2 c.c., respectively, of the suspension of material *directly from the naso*pharynx, tonsils, and so forth, suspended in 2 c.c. of gelatin (0.2 per cent) Locke's solution, or with these amounts of pure cultures of the streptococcus in dextrose-brain broth, diluted in dextrose-brain broth 1:200 or 1:10,000 immediately before injection. In special instances, much higher dilutions (as *high* as 1:100,000,000) of cultures were given intracerebrally, and undiluted cultures were given intravenously and intratibially to rabbits. Monkeys and dogs were inoculated intracerebrally with from 1 to 5 c.c. of cultures diluted 1:200 to 1:10,000. Five-tenths cubic centimeter to 1 c.c. of suspensions of the heat-killed streptococci, ten times the density of broth cultures, or of filtrates of cultures, was inoculated intracerebrally into rabbits.

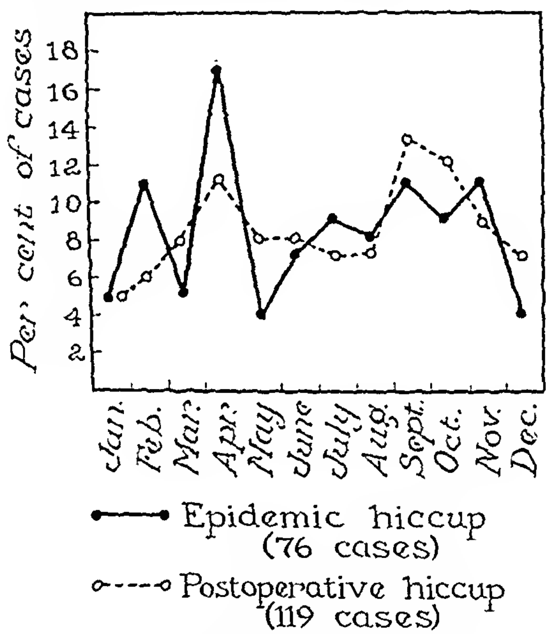

Fig. 1.—Percentage incidence by months of cases of epidemic and postoperative hiccup, Mayo Clinic, 1927 to 1941.

Pure cultures of the streptococcus were obtained from mixtures by making subcultures in rapid succession in previously warmed dextrose-brain broth, and from the end point of growth in serial dilution cultures[12] alternately in dextrose-brain broth and soft dextrose-brain agar (0.2 per cent dextrose and 0.2 per cent agar) and not by plating on blood agar. One or a few additional platings on blood agar usually destroyed the property on which elective localization depends, whereas this property was maintained at the end point of growth of streptococci in serial dilution cultures and after as many as 75 rapidly repeated subcultures in dextrose-brain broth.

Animals were observed two or more times daily after inoculation and their symptoms were recorded. Necropsies were performed as soon as possible after death from the inocula or from ether. Cultures from pipettings of the brain, spinal cord, cerebrospinal fluid, and blood were made routinely in dextrose-brain broth and on blood agar plates. In special instances cultures were made from liver, spleen, kidney, adrenals, muscles, and nerves. Tissues were put aside in 10 per cent solution of formalin for microscopic study.

Cultures were made from the air of rooms occupied by persons having persistent hiccup by exposing open tubes of dextrose-brain broth or by bubbling the air through dextrose-brain broth, chick-mash medium, and dextrose broth for twenty-four to forty-eight hours. For precipitation tests sterile distilled water was likewise exposed in shallow layers in Petri dishes or air was bubbled through water contained in tall columns in test tubes.

SEASONAL INCIDENCE OF EPIDEMIC AND POSTOPERATIVE HICCUP

The occurrence of cases of persistent hiccup in unusual numbers at certain seasons was noted throughout the years of this study (1927 to 1941). There were great variations in severity and duration of the disease and accompanying gastric distress and other symptoms. The great majority of cases studied occurred in men from 17 to 82 years of age. In most instances attacks followed mild, and less often severe, respiratory infections. The seasonal and simultaneous occurrence of epidemic and postoperative hiccup in relation to relatively mild outbreaks of respiratory infections in spring and autumn is well illustrated in Fig. 1.

TABLE I

ERYTHEMATOUS REACTIONS OF PERSONS HAVING PERSISTENT HICCUP TO INTRADERMAL INJECTION OF THE EUGLOBULIN FRACTION OF ENCEPHALITIS AND OTHER ANTISTREPTOCOCCIC SERA

DISEASE GROUPS	CASES	ERYTHEMATOUS REACTIONS TO:						
		EUGLOBULIN FROM STREPTOCOCCIC ANTISERA						NORMAL HORSE SERUM

*The figures above the line in each instance indicate the number of tests; the two sets of figures below the line indicate, respectively, the average reaction in square centimeters and the percentage of reactions measuring 5 sq. cm. or more. Fractions are given to the nearest whole number.

RESULTS OF CUTANEOUS AND PRECIPITATION TESTS

The results from intracutaneous inoculation of persons having persistent epidemic or postoperative hiccup with solutions of the water insoluble or euglobulin fraction of the serum of horses immunized with streptococci isolated in studies of encephalitis, poliomyelitis, epilepsy, arthritis, influenza, and ulcerative colitis are summarized in Table I. The reactions indicate a close relation between the infecting agents of epidemic and postoperative hiccup and epidemic encephalitis. Both the average reaction and the percentage of reactions 5 sq. cm. or more in size in these two groups of cases were greatest to the encephalitis euglobulin, second greatest to the epilepsy euglobulin, third greatest to the influenza euglobulin, and least to the poliomyelitis and arthritis euglobulins. The average reaction and percentage of reactions of 5 sq. cm. or more in the group of cases of influenza were extremely high to the influenza

englobulin and low to the other englobulins. The average reaction and incidence of reactions of 5 sq. cm. or more to the different englobulins were consistently low in the group of normal controls.

The results of precipitation reactions between the encephalitis and other antistreptococcic sera and cleared extracts of nasopharyngeal swabbings and sera of persons having epidemic or postoperative hiccup are summarized in Table II. In accord with epidemiologic and clinical observations, the incidence of positive reactions with sera and extracts of nasopharyngeal swabbings of patients having persistent hiccup was strikingly high with the encephalitis antiserum and moderately so with influenza and epilepsy antistreptococcic sera. Likewise, in the groups of cases of encephalitis and influenza, the reactions were high with the respective homologous antisera and consistently low in the control group of well persons.

*No precipitation occurred with normal horse serum.

†The term "influenza" in this study is used to designate the more severe type of seasonal epidemic respiratory infections.

AGGLUTINATION OF THE STREPTOCOCCUS

The results of agglutination tests with streptococci isolated from atria of infection in cases of epidemic and postoperative hiccup, encephalitis and influenza, and from well persons remote from epidemics are summarized in Table III. A high incidence of specific agglutination occurred with the encephalitis antistreptococcic serum and streptococci isolated from atria of infection of persons having persistent hiccup, and interestingly, the incidence was relatively high with antisera prepared with the closely related streptococci isolated in studies of influenza and the spasm-producing streptococci isolated in studies of epilepsy. Streptococci isolated in studies of encephalitis and influenza were specifically agglutinated by the respective homologous antisera, whereas control strains from well persons were not.

TABLE III

AGGLUTINATION BY ENCEPHALITIS ANTISTREPTOCOCCIC SERUM OF STREPTOCOCCI ISOLATED DURING STUDIES OF EPIDEMIC AND POSTOPERATIVE HICCUP

SOURCE OF STREPTOCOCCI	CASES OR STRAINS	CULTURES	PERCENTAGE INCIDENCE OF SPECIFIC AGGLUTINATION* BY STREPTOCOCCIC ANTISERA FOR					
			ENCEPHALITIS	POLIOMYELITIS	ARTHRITIS	INFLUENZA	ULCERATIVE COLITIS	EPILEPSY

Epidemic encephalitis	96	144	75	9	10	0	0	3
Epidemic influenza	84	84	0	5	5	57		24
Well persons remote from epidemics	49	49	8	4	22	14	0	16

*No agglutination with normal horse serum occurred with any of the suspensions and in some agglutination was nonspecific.

As has been shown, encephalitis streptococcic antigen was demonstrated in the serum by precipitation tests (Table II) and in the skin by intradermal injection of antibody (Table I) during the acute stage of epidemic and postoperative persistent hiccup. As recovery occurred, promptly following therapeutic injection of the encephalitis antistreptococcic serum, and more slowly without serum treatment, the reactivity of serum and skin (antigen) disappeared as specific antibodies became demonstrable for strains of streptococci obtained in studies of hiccup and encephalitis. The results of agglutination tests with convalescent serum are well illustrated by the following observations.

Each of nine sera obtained from persons convalescent from hiccup agglutinated to a greater degree and in higher dilution seven of nine strains of streptococci isolated in studies of epidemic and postoperative hiccup than did nine control sera obtained from patients having arthritis, fibrositis, or influenza. The nine convalescent sera did not agglutinate composite suspensions of streptococci isolated in studies of arthritis, epilepsy, and influenza, respectively. In sharp contrast, the sera from persons having arthritis, epilepsy, or influenza agglutinated specifically the composite suspensions of streptococci isolated, respectively, in studies of these diseases.

ANIMAL EXPERIMENTS

The results obtained on intracerebral inoculation of the living streptococcus, the heat-killed streptococcus, and filtrates of cultures of streptococci in relation to persistent hiccup are summarized in Table IV. It will be noted that the incidence of hyperpnea (49 to 100 per cent) and of spasms of the diaphragm (62 to 88 per cent) and other muscles (65 to 90 per cent) was extremely high, and the incidence of flaccid paralysis (0 to 13 per cent) was very low after inoculation of the living streptococci, corresponding dead streptococci, and filtrates of cultures obtained in relation to hiccup. In contrast, the incidence of spasms of the diaphragm (2 per cent) and other muscles (19 per cent) after inoculation of streptococci from well persons and from indoor air of rooms of persons having poliomyelitis (0 and 57 per cent, respectively) was low. The incidence of flaccid paralysis was extremely low (6 per cent) after inoculation of the streptococci from the group of well persons, and very high (81 per cent) after inoculation of streptococci from indoor air in relation to

cases of poliomyelitis. Specific effects were especially striking after inoculation of filtrates and suspensions of heat-killed streptococci, when ultimate dosage could be controlled better than by inoculating the living streptococci.

The mortality rate varied greatly after inoculation of living streptococci, being highest in animals that received the streptococci from patients having influenza (90 per cent) and in those that received streptococci from air of rooms of persons having epidemic hiccup (87 per cent) or poliomyelitis (86 per cent); intermediate after inoculation of streptococci from throats of patients suffering from epidemic hiccup (58 per cent) or postoperative hiccup (53 per cent), or of well persons remote from epidemics (42 per cent); and lowest (33 per cent) after inoculation of streptococci from milk supplies.

Lesions of the diaphragm, consisting of localized hemorrhages, occurred only in animals that had violent spasms after inoculation of streptococci isolated from persons having persistent hiccup.

Lesions of the lungs, consisting of hemorrhagic edema and bronchopneumonia, occurred most often and, with one exception, were most conspicuous after inoculation of the streptococcus isolated from persons having persistent hiccup or from milk and air in relation to persistent hiccup and influenza. In accord with the frequent occurrence of gastric distress in patients, lesions of the stomach were common and consisted of numerous, small, superficial hemorrhages in the mucous membrane apparently due to violent spasms, and of early, often almost immediate, post-mortem digestion of the wall of the stomach.

The incidence of isolation of streptococci from the brain, the site of inoculation, was relatively high in each group of cases, whereas the incidence of their isolation from blood of animals that died was very low (0 to 9 per cent), with the exception of those inoculated with streptococci from the nasopharynges of persons having acute influenza (67 per cent).

The spasm-producing type of streptococcus was isolated repeatedly from some patients during acute attacks of hiccup but not after recovery. Its presence was demonstrated in persons during recurring attacks over periods as long as four years, in atria of infection in persons having mild but continuous symptoms for as long as two years, and in several protracted cases in which the attending physician considered the spasms of functional origin. In some cases it was isolated from nasopharynx, infected teeth, tonsils, prostatic secretion, urine, stool, or pus from appendiceal abscesses and infected gall bladders.

MICROSCOPIC LESIONS OF THE BRAIN AND SPINAL CORD OF EXPERIMENTAL ANIMALS

Sections of the brain and spinal cord were made and examined for lesions in altogether 39 animals that died from inocula or that were anesthetized after inoculation. The duration of the experiment in these animals was one to two days in 14; three to five days in 15, and six days or longer in 10. Suspensions in gelatin-Locke's solution of nasopharyngeal swabbings and other material directly from patients were inoculated in 12 animals, cultures of living streptococci in 21, dead streptococci in two, and filtrates in four.

The lesions found in animals that died within one to two days after inoculation consisted chiefly of a relatively mild, but never grossly suppurative, polymorphonuclear meningitis, usually most pronounced over the anterior aspect

of the medulla. Perivascular, leucocytic infiltration, degeneration, edema and localized hemorrhages in sulci, choroid plexus, and anterior aspect of the me-

Fig. 2.—Lesions in rabbits in which spasms of the diaphragm developed after intracerebral inoculation of living streptococci isolated from the nasopharynx of a patient having epidemic hiccup: *a*, in the medulla; *b*, in the brain of a rabbit five days after inoculation; *c*, in the medulla of another rabbit three days after inoculation of the same culture (hematoxylin and eosin, ×110).

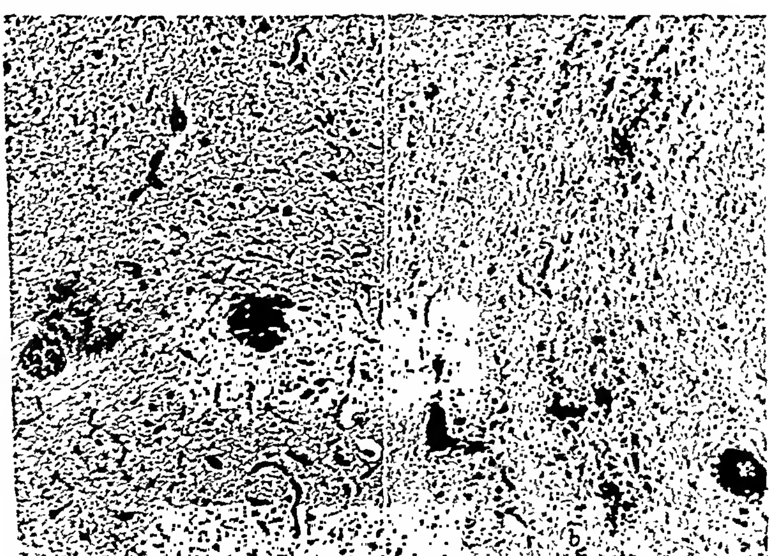

Fig. 3.—Lesions in animals in which spasms of the diaphragm had developed after intracerebral inoculation of living streptococci from the nasopharynges of patients having postoperative hiccup: *a*, in the medulla of a guinea pig six days after inoculation; *b*, in the pons of a rabbit five days after inoculation (hematoxylin and eosin, ×110).

dulla were often conspicuous two days after inoculation of material containing living streptococci, dead streptococci, and active filtrates. Following this, there was a rapid transition from polymorphonuclear cells to lymphocytes,

especially surrounding blood vessels in the pons, floor of the fourth ventricle, medulla, subcortical region, and choroid plexus. This transition in type of infiltrating cells occurred earlier within the parenchyma than in the meninges (Fig. 2). After five or six days typical lymphocytic infiltration, degeneration of ganglion cells (Fig. 3), circumscribed regions of glial infiltration, and other lesions of encephalitis were found. In no instance were the lesions characteristic of spontaneous encephalitis encountered. Necrosis associated with leucocytic and lymphocytic infiltration at the point of injection in the right frontal lobe occurred commonly, but abscess formation was present only occasionally. The lesions remote from the point of injection were essentially alike on both sides. The streptococci were readily demonstrable, especially as diplococci, in the lesions of animals that died soon after inoculation. As lymphocytic infiltration became marked, their demonstration became difficult and often impossible (Fig. 4).

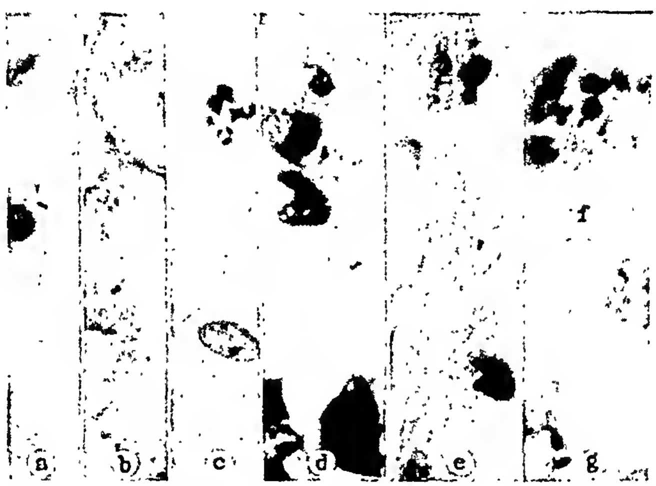

Fig. 4.—Diplococci in the lesions of rabbits and guinea pigs in which spasms of the diaphragm had developed after inoculation of living streptococci (*a*, *b*, *c*, *d*, and *f*) and heat-killed streptococci (*e* and *g*) isolated in studies of epidemic and postoperative hiccup (modified Gram stain, ×1,000).

SERUM TREATMENT

Serum treatment was given only after the usual methods, such as administration of carbon dioxide, gastric lavage, and sedatives, to control the spasms had proved of no avail. The whole, unconcentrated encephalitis antistreptococcic serum was used at first, whereas later the refined serum of similar antibody content, consisting of solutions of one part of the euglobulin and two parts of the pseudoglobulin, was used. After determining that the patient was not allergic to horse serum, and after desensitization if he was found sensitive, 10 c.c. of the serum were injected deeply into the muscles of the buttock twice daily until the hiccup had disappeared, and usually one additional injection was given after that. The concentrated encephalitis antiserum and the euglobulin solution for the cutaneous test, first prepared by me, are now being made available for study by the Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Ind.

Records of results from the use of encephalitis antistreptococcic serum in treatment have been obtained in altogether 90 cases of persistent hiccup. Fifty-four of these were considered as cases of epidemic persistent hiccup and 36 occurred postoperatively. The results from the use of the serum were so similar in the two groups of cases that they will be considered as one group.

The ages of the patients ranged from 7 to 82 years. The great majority were more than 50 years of age. In all but two postoperative cases, and all but six of the nonoperative cases the patients were men, a proportion of approximately ten men to one woman. The duration of the disease at the time of the first serum treatment was from one to twenty-one days in acute cases, as long as two years in persons having continuous hiccup, and four years in those having recurring attacks. The amount of serum given ranged from 10 to 110 c.c., usually 20 to 40 c.c.

Detailed records regarding noteworthy diminution of severity and number of spasms and cessation of hiccup in relation to the number of injections of serum were available in 60 cases. Reduction of severity and number of spasms was noted after the first injection of serum in 20 cases, after two injections in 21 cases, and after three or more injections in 12, whereas in seven cases no apparent benefit followed soon after injections of serum. Cessation of spasms occurred after the first injection in 14 cases, often within several hours; after two injections in 16 cases, after three injections in nine, and after four injections in 10 cases. In the remaining seven cases in which the patients survived, the hiccup disappeared after from seven to ten days during the period of sensitization. In four postoperative cases no apparent beneficial effects were noted after the administration of the serum. Two of these patients died: one, a man 78 years of age, from cardiac failure following suprapubic prostatectomy in the presence of a badly infected bladder; the other, a man 72 years of age, from peritonitis following strangulated hernia. In the other two, hiccup occurred after prostatectomy, continued for two weeks, and then gradually disappeared.

Immediate serum reactions did not occur in any case. In 15 there were late serum reactions and of these only five were severe.

In the 36 postoperative cases 11 patients had had prostatectomy; two, cystoscopy; five, appendectomy with appendiceal abscess; three, colostomy; seven, cholecystectomy; two, herniotomy; one, gastrectomy; two, rectal resections for carcinoma; one, nephrotomy; one, septic hip; and one, tonsillectomy. There was great variation in the effects of the serum after its injection. The sudden permanent cessation from one or two injections, after every other known means had failed to give relief, often in patients severely exhausted, was so convincing as to leave little doubt of the curative action of the serum. The earlier the serum was given, the more prompt was the relief. The cessation of hiccup after administration of the serum was not coincidental because usually more injections were necessary late in the course of attacks than when given early. Prompt relief after administration of the serum was often associated with striking diminution in reactivity of the skin on reinjection of the encephalitis euglobulin and a negative precipitation reaction with the patient's

serum. This was true of both the nonoperative and operative cases. These observations are in accord with the results of treatment reported by Mayo, assisted by Rozendaal, who stated:

"That there is a relationship between the organisms of epidemic encephalitis and of epidemic hiccup is fortunate, because the encephalitis antibody globulin solution as prepared by Rosenow can be applied in treatment. Such treatment was given in those of our cases in which persistent hiccup was present, and we were able to recover the neurogenic streptococcus from the throat and reproduce spasms in animals. The effect of the serum was dramatic in many instances, all symptoms of hiccup disappearing within a few hours."

Most of the patients whom I saw had badly infected teeth or other evident foci of infection. There was definite correlation between focal and metastatic infection and the response to serum treatment. In general, the worse the infective process, the longer were injections of serum necessary to control the hiccup. This was especially true in cases in which there was surgical drainage after operative treatment of suppurative appendicitis, cholecystitis, and prostatitis associated with cystitis. In several cases in which the diagnosis was functional hysterical hiccup, the spasm-producing streptococcus was isolated from the nasopharynx and prompt relief followed administration of the serum.

As in epidemic encephalitis and poliomyelitis, there has been found a much higher incidence of cases of persistent hiccup—a mild form of myoclonic encephalitis—among men than among women, indicating an inherent susceptibility of men to the inciting agents of these diseases.

COMMENTS AND CONCLUSIONS

The results of previous studies have been corroborated and extended. The isolation of the spasm-producing type of streptococcus from the nasopharynx, milk supplies, and outdoor air during epidemic prevalence of hiccup and certain respiratory infections and from the air of rooms occupied by persons having persistent hiccup, and the absence of this type of streptococcus remote from hiccup, indicate that epidemic hiccup and postoperative hiccup occur in increased incidence when streptococci normally present in throats of persons and in nature generally acquire spasm-producing properties or virulence.

Persistent epidemic hiccup and persistent postoperative hiccup are considered as forms of mild myoclonic encephalitis. The inciting agent is a streptococcus *(Streptococcus singultus)* closely related to the streptococcus isolated in studies of epidemic encephalitis and the antistreptococcic serum for epidemic encephalitis is curative in persistent hiccup.

CIRCULATING TIME IN THE HUMAN BEING AND IN THE DOG AS AFFECTED BY FASTING AND BY MEALS*

I. M. Reingold, M.D., F. Neuwelt, M.D., and H. Necheles, M.D., Ph.D.
Chicago, Ill.

Our laboratory has been interested in the use of determinations of circulating time in the state of shock.[1] We were interested, therefore, in the normal variations of circulating time during fasting and following the ingestion of various foods. Our results obtained differ from those of another group.[7, 8]

Various reports in the literature indicate that there is a considerable change in circulation during digestion in man. According to Grollman[2] and others, a significant increase in cardiac output occurs in man after ingestion of food and even of water. Booth and associates[3] reported an elevation of skin temperature in normal subjects following a meat meal. Herrick and associates[4] did not obtain an increase of surface temperature in dogs following ingestion of foods.

In 1934 Herrick and associates[4] reported a notable increase in blood flow in the femoral, carotid, and mesenteric arteries, and in the external jugular vein of the dog following ingestion of various foods. The time of the onset and the duration of the increased flow were influenced by the character of the food taken, but the magnitude of increase was relatively the same regardless of the type of food. These results were confirmed in the human being by Burton and Murlin.[5] Abramson and Fierst,[6] working on human subjects, did not find significant changes in the rate of peripheral blood flow following a carbohydrate meal, but with a protein meal the rate of blood flow increased one and one-half to three hours after ingestion, first in the hand, and later in the forearm and leg.

In 1934 Sheard and co-workers[7] reported experiments in which the circulating time of the blood of dogs was reduced 20 to 35 per cent during digestion of a mixed meal. The lowered circulating time coincided with increases in blood flow measured simultaneously. The method used by these workers consisted in the injection of radium C into the jugular vein and the measurement

*From the Department of Gastro-Intestinal Research, Michael Reese Hospital, Chicago. Supported by the Emanuel Friend Fund.
Received for publication, June 29, 1942.

of the interval of time between the injection and the arrival of the radium below an ionization chamber located over the femoral artery. In 1936 they confirmed these results.[8]

METHODS

In the work reported here we have used the sodium cyanide method for the determination of circulating time, as first described by Loevenhart and associates[9] and as applied by Robb and Weiss to the human being.[10] The cyanide method consists of the intravenous injection of a small quantity of sodium cyanide and the measurement of the time elapsing between the injection and the first response of the chemoreceptors of the carotid sinus which stimulate respiration. In the dog 1 mg. of sodium cyanide dissolved in 0.5 c.c. of saline was injected into the saphenous vein of the hind leg, and in man 8 mg. of sodium cyanide in ⅓ c.c. of saline solution was injected into the antecubital vein. The injection was given rapidly, and two stop watches were started at the time of injection. At the height of the first deep gasp one of the stop watches was arrested. The time obtained was considered to be the circulating time of the blood between the peripheral vein and the carotid sinus. The reaction consisted of a series of rapid and deep respirations. Two stop watches were used because an occasional deep breath not followed by a series of rapid and deep respirations might yield a false end point, which could be corrected by the use of the second stop watch when the series of rapid and deep respirations began.

The human subjects and the animals were starved for at least twelve hours. The experiments on the dogs were performed on two healthy animals and those on the human subjects, on workers in the laboratory, and on such patients of the wards who had undergone simple operations and were ready to be dismissed, and on such patients in whom the circulatory system did not seem to be affected by the disease. The ages of the subjects varied between 16 and 79 years, with an average of 49 years. Most of the human subjects were lying in bed during the experiments, and a few were up and around. The dogs were in a stall during the entire experiment.

A meal was administered after one or more control determinations of the circulating time had been performed, and determinations were repeated at various intervals following ingestion of the meal. One group of subjects was followed over a prolonged period of time without administration of food. The meals administered consisted of protein foods (steaks), or of a regular full hospital diet, or of carbohydrate and fat foods. The amounts eaten were about those of a good average luncheon and varied somewhat according to the appetite of the subject. The dogs were fed one pound of a commercial dog food containing meat, oats, and vegetable, mixed with water.

Twenty-nine experiments were performed on 21 different subjects: 17 males and 4 females. Twelve experiments were performed on 12 different fasting subjects and are recorded on the upper part of Chart 1. Six experiments were performed on two dogs.

RESULTS

A. In Human Subjects.—Fasting circulating times varied between 12 and 22 seconds, with an average of 17.2 seconds (34 tests). Controls before meals varied between 12 and 29 seconds, with an average of 17.6 seconds (31 tests).

Circulating times following all meals varied between 10 and 26.6 seconds, with an average of 17.5 seconds (48 tests). Analysis of the data did not reveal significant differences in the changes of circulating time following the various meals. In order to illustrate the wide variations of circulating time during fasting and following meals, we have expressed all data as per cent changes from the first determination in the fasting subjects and from the last determination before the meal in the postprandial subjects. We have chosen this method of presentation of our data because the variations observed during the fasting and the postprandial states seemed to be due to cyclic changes.

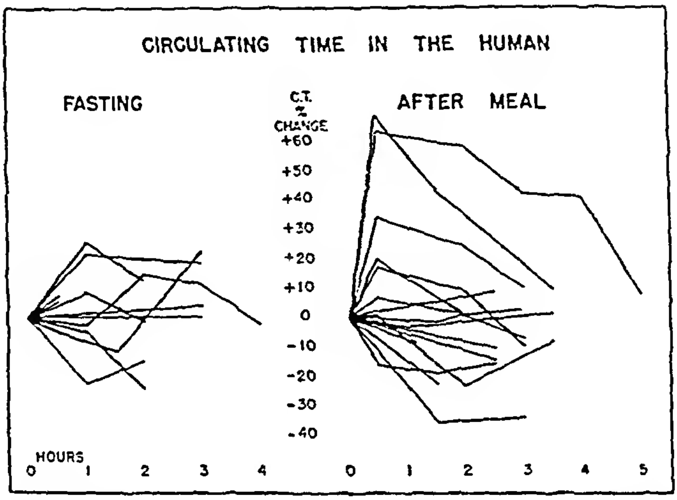

Chart 1.—Circulating time in the *fasting* human subject in per cent changes from first determination. Circulating time *after meal* in per cent changes from last determination before meal.

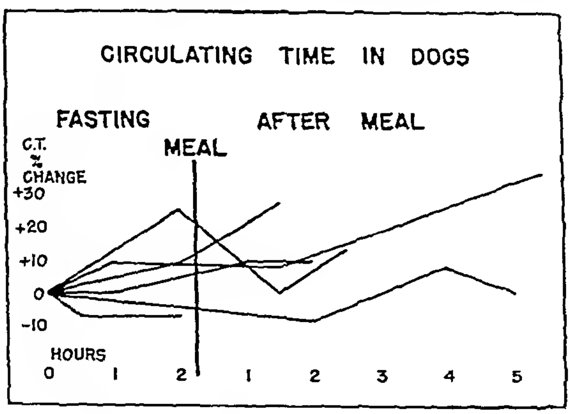

Chart 2.—All circulating times in per cent changes from first determination made.

In most of the fasting subjects variations between −25 and +25 per cent from the control reading were obtained, while in only a few of the fasting subjects circulating time did not vary appreciably during the periods of observation of thirty minutes to four hours.

Seventeen experiments following ingestion of food are recorded on the right side of Chart 1. Circulating time varied between a diminution of 36 per cent and an increase of 67 per cent of the control values. The spread of the

data is greater than that seen during fasting, but this is due to a greater variation in circulating time in *only 2 of these 17 experiments.*

B. In the Dog.—Values of circulating time before the meal varied between eight and fourteen seconds, with an average of twelve seconds. (12 tests), and after the meal they varied between eight and fifteen seconds, with an average of 12.2 seconds (11 tests). Chart 2 illustrates that essentially the same results were obtained in the dog as in the human being. The circulating time was not constant during periods of two hours of fasting and did not show uniform changes in any direction during periods of one and one-half to five and one-half hours following ingestion of the protein meal.

DISCUSSION

Our results indicate that circulating time varies considerably during fasting as well as following ingestion of various foods. These variations were not uniform in direction, and prolongation as well as shortening of circulating time might occur. From the distribution (spread) of data, as well as from the algebraical averages we assume, therefore, that the changes of circulating time following a meal are not any more significant than are those during fasting. The variations of the individual curves during fasting as well as following meals may be due to cyclic variations in circulating time, rather than to specific causes, such as anxiety, the *postabsorptive state*, etc. If it can be proved that this is due to cyclic variations in circulating time, it will make the simple use of this method uncertain for a number of clinical determinations. The use of the method is not without value in selected conditions, however, as, for example, in the state of shock, where we have described changes far beyond those observed in normal dogs.[1]

We cannot explain the difference between our results and those of the Mayo group.[7, 8] Of course, the two methods are entirely different, and it is possible that they are affected differently during the absorptive state. The sensitivity of the chemoreceptors of the carotid sinus is so great that differences in their response to cyanide constitute only a small fraction of the total circulating time,[1] and we feel that a meal could not affect these receptors so much as to change the total circulating time to any extent. There may be other factors at work, however, such as changes of the circulating volume or of the hematocrit-plasma ratio during the absorptive state, or differences in the carriers (red blood cells or plasma) of the different agents employed, which may affect both methods differently. Besides, it was not apparent from the report of the Mayo group whether prolonged control periods during starvation had been instituted and had been compared with the variations of circulating time following meals.[7] In another paper, however, this group reported considerable variations of the circulating times in individual fasting dogs.[11]

The reported constant differences between the cyanide method and arm-to-tongue methods[12] would not seem to affect our findings.

We feel that our results are also of importance because the type of method employed in our study for determination of circulating time belongs to those in common use.

SUMMARY

The circulating time was determined in a group of human subjects and in dogs. The sodium cyanide method of Loevenhart and associates was employed. During the fasting condition considerable variations of circulating time were found in the human being and in the dog, and following meals the same or somewhat greater variations in circulating time were obtained. Our results indicate no significant or uniform changes in circulating time in any one direction in either the fasting or the postprandial state. The nature of the meal did not seem to determine changes in circulating time. The significance of our findings and the discrepancy of our results from those of other workers are discussed.

RECURRENT ATTACKS OF PNEUMOCOCCIC PNEUMONIA TREATED WITH SULFONAMIDES*

LEON SCHWARTZ, M.D., HARRISON F. FLIPPIN, M.D., AND
JEFFERSON H. CLARK, M.D., PHILADELPHIA, PA.

RECURRENCE is more commonly seen in pneumococcic pneumonia than in any other acute infectious disease.[1] Likewise, the attack rate of pneumococcic pneumonia is higher in those persons who have had previous attacks of the disease.[2] The reported incidence of one or more previous attacks varies greatly throughout the world, although most American authorities have noted recurrences in approximately 15 per cent of cases. Furthermore, it is the opinion of many writers[3, 4] that the number of previous attacks of pneumococcic pneumonia does not influence the prognosis of the disease. Within the past four years the treatment of pneumococcic pneumonia has been revolutionized as a result of the advent of the sulfonamide compounds. It is too early to predict whether the widespread use of these drugs will have any effect upon the above-mentioned facts concerning recurrent pneumococcic pneumonia, since it will be necessary to accumulate extensive data from different sources over a period of years before an evaluation can be attempted. However, of equal interest is whether these chemotherapeutic agents are as effective when employed for repeated attacks of pneumococcic pneumonia and whether the patients tolerate the sulfonamide drugs as well during subsequent administrations. The purpose of this study is to present the comparative therapeutic effectiveness and toxicity of the sulfonamides in recurrent pneumococcic pneumonia.

During the past three years we have observed in a series of 1,400 adult pneumonias 24 patients who received sulfapyridine, sulfathiazole, or sulfadiazine on two or more occasions for pneumococcic pneumonia. In every instance the patient was discharged from the hospital fully recovered from pneumonia; and, in order to eliminate possible cases of relapse, we have excluded those readmitted within four weeks following discharge. The diagnosis of pneumonia was established in every case, and a pneumococcus was recovered from the sputum or blood in all patients, although a specific pneumococcus type was not always obtained.

As indicated in Table I, there was a total of 49 hospital admissions in this group of 24 patients. The time interval between admissions ranged from four to ninety-two weeks, with an average of thirty-seven weeks. The patients' ages varied from 14 to 74 years, with 58.3 per cent of the cases being over 40 years of age. Typable pneumococci were found in the sputum or blood stream in 35

*S-P = Sulfapyridine. S-D = Sulfadiazine. b = Positive blood culture.
S-T = Sulfathiazole. †4a = Third admission.

instances. The same pneumococcus type was the causative agent for subsequent attacks in only 4 patients. Positive blood cultures were obtained in 4 patients on the initial admission and in 2 patients on subsequent admission to the hospital. In 14 patients the same lobe of the lung was involved during each attack of pneumonia, and in 9 of this subgroup an additional lobe was involved. There was no appreciable difference in the total number of lobes involved during the initial and subsequent attacks.

Sulfapyridine was employed in 17 patients during their first admission, and of this number 8 received the same drug on nine subsequent admissions. The remainder of this subgroup received sulfathiazole (7 patients) or sulfadiazine (2 patients). Seven patients were given sulfathiazole on their first admission, and of these 2 received sulfapyridine, 2 sulfathiazole, and 3 sulfadiazine on other admissions. Good therapeutic response to treatment with these drugs was determined by a critical fall in temperature within forty-eight hours, a return to normal temperature within forty-eight to seventy-two hours, and by the findings on physical examination. On this basis we have designated the results of treatment as good, fair, or died. There were 2 deaths (8.0 per cent mortality) in this group of 25 subsequent admissions, both occurring in patients with type III infection. This mortality rate compares favorably to that in a larger series of cases of pneumococcic pneumonia treated with sulfonamides reported from this hospital.[5] Of the 22 patients surviving both attacks of the disease, the results of treatment were considered good in 15 on their first admission and in 20 during subsequent courses of therapy with these drugs. This difference in therapeutic response on the different admissions is of no statistical significance.

The incidence of severe toxic reactions due to the drugs is very small in this series. Vomiting and microscopic hematuria constituted the only toxic manifestations worthy of mention. In comparing these toxic effects it should be pointed out that the selection of drug undoubtedly influenced the incidence of toxicity in these cases. However, it is of interest to note that none of the more serious toxic reactions developed on subsequent use of the same drug or of other members of this group of drugs. Not included in this series of cases is a patient recently treated by one of us (H. F. F.) for pneumonia with sulfadiazine who showed no apparent ill effects from the drug; this patient had on a previous occasion developed a severe skin reaction as a result of sulfathiazole medication.

In view of the data presented in this report it would appear that the use of the sulfonamides in a previous attack of pneumococcic pneumonia does not alter the response to the same drug or to similar drugs when used in subsequent attacks of the disease. Also, the incidence of toxic reactions is no greater when these drugs are employed for repeated attacks of pneumococcic pneumonia. Further study of similar data on a larger series of cases receiving the same drug for two or more attacks of pneumococcic pneumonia is desirable.

SUMMARY

1. Twenty-four adult patients have been given sulfonamide therapy on two or more occasions for recurrent pneumococcic pneumonia.

2. The drugs seemed just as effective when administered for subsequent attacks of the disease as during their initial use.

3. There is no evidence to suggest that the repeated use of the sulfonamides for recurrent pneumococcic pneumonia increases the incidence or severity of drug toxicity.

ERYTHROCYTE SEDIMENTATION RATE DETERMINATIONS ON NORMAL YOUTHS

C. Frederic Roche, M.D., F.A.C.P., Donald G. Stannus, M.D., and Emil M. Isberg, M.D., Miami Beach, Fla.

The erythrocyte sedimentation rate is an accepted laboratory measure of pathologic activity, and the range of normal values for the various techniques has been determined by numerous investigators over the country. Rourke and Ernstene found the normal range of "corrected sedimentation index" to be 0.08 to 0.35 mm. per minute, based on the results of 92 measurements done on 45 different healthy persons.

In order to ascertain what is the range of normal in this community, determinations were done on 100 normal youths, all students at the junior high school and high school here. A careful history and physical examination were done on each subject, and only those found to be in good health were included in the series. Any history of recent infection, common cold, tonsillitis, dental infection, sinusitis, etc., excluded the potential subject. Of the 100 healthy youths in the series, 60 were males and 40 were females. Their ages ranged from 11 to 17 years.

The temperature of each subject was recorded, and all blood specimens were obtained at least two hours after the previous meal. Extreme care was taken in order that blood be withdrawn from the vein with as little stasis as possible. Any apprehension or excitement on the part of the subject at the time the specimen was withdrawn was recorded. The date on which the last menstrual flow ceased was noted for each female subject.

The Rourke-Ernstene corrected sedimentation technique was used exclusively. Each determination was made within two hours after the blood speci-

Received for publication, July 6, 1942.

men was obtained. Heparin was used as the anticoagulant. Every sedimentation tube was handled with a minimum amount of manipulation. Precautions were taken to see that the sedimentation tubes were in absolute vertical position. The temperature and humidity of the laboratories and the barometric pressure were recorded. Sixty-two determinations were done in the St. Francis Hospital laboratory, which is not air-conditioned, and the remaining 38 tests were done in an air-conditioned laboratory.

The corrected sedimentation rates of the 100 normal youths ranged from 0.09 mm. per minute to 2.0 mm. per minute. The mean rate was 0.46 mm. per minute. Seventy-five per cent of all the determinations were below 0.65 mm. per minute. Rourke and Ernstene[1] placed the value of 0.35 mm. per minute as the upper limit of normal. Yet 53 per cent of all the readings in this series fell in the range between 0.35 and 0.65 mm. per minute. The mean rate for girls was 0.47 mm. per minute, and for boys it was 0.46 mm. per minute.

We could not determine the reason that the sedimentation phenomenon should be more rapid in a subtropical climate. Numerous investigators have shown that low temperatures retard and high temperatures accelerate the rate of sedimentation of erythrocytes. The barometric pressure varied from 760 mm. to 770 mm.

Forty-four volumes per cent was found to be the mean hematocrit value for both males and females in our series. Rourke and Ernstene have set 45 volumes per cent as the mean value for correcting the sedimentation rate. Forty-nine volumes per cent was the highest value for females in the series, while 11 of 60 males had hematocrit values of 50 to 52 volumes per cent.

CONCLUSIONS

1. The erythrocyte sedimentation rates of 100 normal Miami Beach youths were determined according to the Rourke-Ernstene technique.

2. The rates of 75 per cent of the series ranged from 0.09 to 0.65 mm. per minute, and 53 per cent of the series ranged from 0.35 to 0.65 mm. per minute.

3. We propose that the upper limit of normal for the Rourke-Ernstene corrected sedimentation index for South Florida be extended to 0.65 mm. fall per minute.

4. Since it has been proved by other workers that the various methods for determining erythrocyte sedimentation rate are reasonably the same, we suggest that the range of normal for other techniques also be extended for this locality.

PAPILLARY LYMPHOID CYSTADENOMA*

Report of Four Cases

Hyman Peck, M.D., Hines, Ill.

AMONG tumors of the salivary glands one of the rarest is papillary lymphoid cystadenoma. Other terms by which it has been described include papillary adenolymphoma, papillary cystadenoma lymph glands, papillary cystadenoma lymphomatosum, branchiogenic cystadenolymphoma, branchiogenic adenoma, branchioma, and onkocytoma. Papillary lymphoid cystadenoma is probably the most descriptive name for the tumor.

The tumors were first described by Albrecht and Arzt (1910), Glass (1912), Ssobolew (1912), and Feldman (1916). In 1935 Carmichael, Davie, and Stewart reviewed the literature and found 26 cases reported up to that time in twenty-one papers. They described 8 new cases. Subsequently, five more cases appeared in the American literature,[6, 8, 9, 11] and seven in foreign language publications.[10-16]

The genesis of these tumors has been variously ascribed to heterotopic salivary gland tissue in lymph nodes,[3, 4] heterotopic pharyngeal epithelium,[17] and to branchiogenic rests.[18] The great majority of the tumors are first noticed in the fifth or sixth decade, and they are found only in close relation to the parotid and submaxillary glands and at the angle of the jaw. No case has been noted in association with the sublingual glands. They are six or seven times more common in males than in females. Only two of the cases have been stated to be malignant. One tumor reported by Oden[6] showed enough active proliferation and loss of polarity of the cells to be possibly a transition stage between benignity and malignancy. Only one case was reported in which there was a local recurrence and this appeared in three years.

In the surgical biopsies of Hines Hospital during the past two years five cases of papillary lymphoid cystadenoma were found. One of these has been reported by Hines.[11] All of them were benign.

CASE REPORTS

Case 1.—The patient, W. S. D., was a white male, aged 51 years. One and a half years before admission to the hospital he noticed in the preauricular area on the right a small lump which had grown progressively larger. On physical examination this mass was small and movable.

At operation the tumor was enucleated from under the capsule of the parotid gland. Another smaller nodule was then found adjacent to the one previously removed, and it was also removed. The tumors measured 2 by 1 by 1 cm. and 1.5 by 1 by 0.5 cm.

Case 2.—Three and a half years before admission to the hospital a white male, A. J. K., aged 49 years, observed in the right parotid region a growth which gradually

*From the Clinical Laboratory Center, Veterans' Administration, Hines, Ill.

Published under R & P 6227.
Received for publication, July 13, 1942.

increased in size. No discomfort or pain was associated with the lesion. He was operated on at another hospital, and a partial excision was done. The biopsy diagnosis was made there of adenoma of the parotid with malignant change. Upon admission to the hospital for further therapy one month later a soft 2 cm. mass was found in the right parotid area. The tumor was raised 1.5 cm. above the skin. Sialogram revealed filling of the ducts of the parotid gland which was compressed by the external tumor.

At operation a nodule was found in the substance of the parotid gland. The tumor was completely encapsulated and easily enucleated. It measured 4.5 by 2.5 cm.

Case 3.—Patient, R. C. B., a white male, aged 48 years, noticed a small lump behind the left ear, five months before admission to the hospital. The mass was about the size of a pecan and had grown steadily larger. The patient experienced no pain and no increase in salivation.

Physical examination revealed a 5 by 4 cm. mass in the left parotid region. The overlying tissues were freely movable, but the tumor appeared to be somewhat fixed to the underlying structures. No adenopathy was present.

At operation the tumor was found to be within the parotid gland substance but well encapsulated and easily enucleated. It measured 5.3 by 3.5 by 2 cm., felt cystic, and had small satellite nodules at the periphery.

Case 4.—The patient, G. F. J., a white male, aged 46 years, noticed a mass behind the angle of the left jaw three years before admission to the hospital. This became progressively larger. The nodule was asymptomatic.

Physical examination revealed a tumor the size of a walnut behind the angle of the left jaw. The skin was freely movable over it. The mass was slightly movable but was apparently attached to, and was part of, the parotid gland underneath.

At operation this mass was found in the lower pole of the parotid gland. It was encapsulated and was easily enucleated. It measured 4 by 3 by 2 cm.

The preoperative duration in our cases was eighteen months, forty-two months, five months, and thirty-six months, respectively, and averaged twenty-five months. The tumors were in the substance of the parotid gland in three cases and just under the capsule in the first case. None of the masses were painful or tender. The tumor was not attached to the skin in any of the cases. The right and left parotid areas were equally affected in frequency. The preoperative diagnosis in three cases was mixed tumor of the parotid gland. In our second case the preoperative diagnosis was adenoma of the parotid with malignant change. All the tumors were well encapsulated and easily removed.

The capsule of the tumors was thin, fibrous, and had small vessels on its surface. The color varied from a reddish brown to a reddish gray. There was a small nodular character to the surface. The tumors were cut with ease and the sectioned surface was finely granular and showed small cysts filled with serous or colloid material which upon formalin fixation became an opalescent pearly gray. The specimen in our first case, however, showed no cysts grossly.

Histologically the tumors were cystic with papillary structures. They were composed of a double layer of columnar epithelial cells which formed tubular alveoli or clefts, and cystic spaces with slender and branching papillary projections. The cells were pale and under low magnification the cell outlines were difficult to make out. Goblet cells were very prominent and numerous in the fourth case and appeared occasionally or were absent in the other cases. The basal cells were smaller, irregular, and lay close to the basement membrane. In places the cells were multilayered. The nuclei were round to oval and had a delicate chromatin network. Some of the nuclei were indented. The nuclei had

Fig. 1.—Gross appearance of papillary lymphoid cystadenoma in fourth case.

Fig. 2.—Structure of papillary lymphoid cystadenoma in fourth case, showing double layer of lining epithelium, papillary structure, and lymphoid follicles in stroma. Magnification ×150.

one or two nucleoli. The epithelium rested upon a thin membrane which seemed to fuse with the delicate reticulum of the stroma in the center of the papillae. The stroma was infiltrated by many lymphocytes, with the formation of lymph follicles having large reaction centers. The cells were not ciliated. However, adherent masses of secretion gave a false appearance of cilia under low magnification.

The material in the cysts consisted of granular precipitate with desquamated epithelium, lymphocytes, phagocytes, fat, and cholesterol.

SUMMARY

1. Of 6,239 surgical biopsies in Hines Hospital four cases of papillary lymphoid cystadenoma were encountered.

2. All four cases showed considerable consistency in clinical and gross and histological characters.

3. The clinical features were a painless and otherwise asymptomatic slow-growing mass in close association with the parotid gland. The overlying skin was movable and no ulceration occurred. The tumors were completely encapsulated and easily enucleated and they did not recur.

4. The gross appearance was characterized by a somewhat nodular capsule and a finely granular cut surface on which cysts could usually be easily seen.

5. The histology was characteristic and essentially consisted of papillary structures with a double layer of cells lining cystic spaces. The core of the papillae was made up of a reticulum infiltrated with lymphocytes forming follicles having large reaction centers.

THE SIGNIFICANCE OF THE ELECTROCARDIOGRAM WITH PROMINENT S WAVES IN LEADS I, II, AND III*

M. WILBURNE, M.D., AND R. LANGENDORF, M.D.
CHICAGO, ILL.

ASHMAN and Hidden[1] have recently directed attention to an electrocardiographic pattern exhibiting prominent S waves in Leads I, II, and III. Eight of their 29 cases revealed no demonstrable heart disease, and 7 of their 8 cases showed no electrocardiographic changes other than the deep S waves. In all 8 cases the patients had a vertical or normally placed heart. Only one subsequent reference (Ashman and Hull[2]) to this type of electrocardiogram has appeared in the literature so far as we know.

It seemed desirable to investigate this pattern further in order to evaluate its frequency and significance. A total of 1,850 consecutive electrocardiograms from the Heart Station of Michael Reese Hospital were reviewed. Prominent S waves (defined below) in Leads I, II, and III were present in 84 of these cases (4.5 per cent). The ages represented in the 84 electrocardiograms ranged from 4 to 77 years inclusive. Fifty-nine persons were males and 25 were females.

TABLE I

CORRELATION OF CLINICAL FINDINGS WITH ELECTROCARDIOGRAMS EXHIBITING PROMINENT S WAVES IN LEADS I, II, AND III

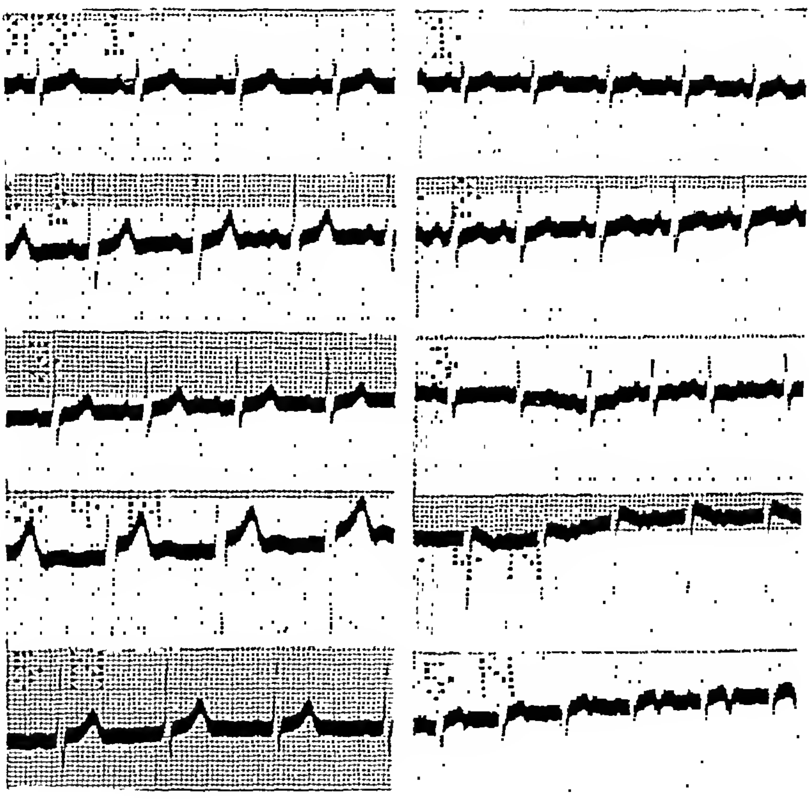
CLINICAL FINDINGS	TOTAL NO. OF CASES 84	ELECTROCARDIOGRAM		
		NORMAL* (GROUP A) 35	QUESTIONABLE (GROUP B) 8	ABNORMAL (GROUP C) 41
No demonstrable heart disease	28	19	4	5
Questionable heart disease	10	3	1	6
Definite heart disease	46	13	3	30

*See criteria in text.

The electrocardiograms were divisible into three groups: Group A, in which no additional deviations from the currently recognized normal electrocardiogram were found—35 cases; group B, in which the electrocardiograms showed changes which were considered questionably abnormal—8 cases; and group C, in which the electrocardiograms revealed definite abnormalities—41 cases. The relationship of this pattern to the presence of heart disease in these three groups is summarized in Table I, and their distribution by age groups is shown in Table II.

*From the Cardiovascular Department, Michael Reese Hospital, Chicago.
Aided by the A. D. Nast and Emil and Fanny Wedeles Funds for Cardiovascular Research.
Received for publication, July 13, 1942.

The electrocardiograms considered to be of the otherwise normal S type (Fig. 1) were those exhibiting (1) prominent S waves* in Leads I, II, and III, (2) absence of a prominent Q wave,† and (3) absence of other electrocardiographic changes. The criteria employed to differentiate the otherwise normal S type from the abnormal patterns were: (1) QRS of normal duration; (2) QRS_1 mainly upright, or small and equiphasic; (3) QRS_2 mainly upright; (4) S_2 deeper than S_3; (5) normal S-T-T complex in all limb leads; (6) CF_2 and CF_4 normal,‡ and (7) absence of low "voltage." In all the otherwise normal S type of records QRS in the limb leads was largest in Lead II. The 35 cases in group A fulfilled the above requirements. Those in groups B and C did not.



A. *B.*

Fig. 1.—Five lead electrocardiograms of the otherwise normal S type showing Leads I, II, III, CF_2, and CF_4. Record *A* is that of a normal adult and record *B* of a normal child. Note the prominent S waves in Leads I, II, and III, and the absence of other deviations from the normal. The T-wave changes in Leads CF_2 and CF_4 in *B* are normal in a child. QRS in CF_2 is diphasic but the upright phase is not clear in the reproduction.

Of the 13 cases in group A in which heart disease was known to be present, there were 5 patients with clinically quiescent rheumatic heart disease and suspected mitral insufficiency, 4 with angina pectoris, 2 with chronic cor pulmonale, one child with a first attack of acute rheumatic fever, and one child with postscarlatinal myocarditis.

---

*Final inverted phase which is 25 per cent or more of the upright phase of the QRS complex.

†Initial inverted phase which is 25 per cent or more of the upright phase of the QRS complex.

‡Three of the 84 electrocardiograms had no chest leads; two records had only one chest lead (CF_2); the remaining 79 had two chest leads (CF_2 and CF_4).

The abnormal electrocardiograms exhibiting S waves in the limb leads, represented by the 41 cases of group C, were divisible into 5 major patterns: (1) left ventricular preponderance, (2) right ventricular preponderance, (3) combined right and left ventricular strains,[3-5] (4) myocardial infarction, and (5) nonspecific patterns. In Table III is presented a summary of the various types of patterns encountered in the abnormal electrocardiogram of group C. The most frequent abnormalities encountered in the nonspecific patterns were S-T depressions in the limb leads, splintering and inversion of the QRS complex in Leads CF_2 and CF_4, inversion of the T wave in CF_2 and CF_4, and low "voltage."

DISCUSSION

Records with deep S waves, in Leads I, II, and III were thus encountered in 4.5 per cent (84 cases) of the 1,850 consecutive electrocardiograms reviewed; 2.2 per cent (41 cases) revealed electrocardiographic abnormalities other than the S-type pattern, indicating a definitely abnormal record; and 0.5 per cent (8 cases) showed borderline electrocardiographic variations. In 1.9 per cent (35 cases) no additional deviations from the normal were noted. This last group was labelled the otherwise normal S type. In 19 cases, or more than half of this group, this pattern occurred in patients with no demonstrable heart disease. The probabilities are that the percentage of normal hearts in this group would be much greater in a random sample of the population than in the one selected for this study, since the percentage of normal hearts included would have been much greater.

This otherwise normal S type of electrocardiogram (in which prominent S waves are present in the three limb leads without other deviations from the currently recognized normal electrocardiogram[6]) is thus encountered in ap-

proximately 2 per cent of records in electrocardiographic files. The question arises as to whether the otherwise normal S type of electrocardiogram should be regarded as a normal variant frequently observed in cardiac disease, or as an abnormal pattern often seen in the absence of evidence of heart disease. It appears to us that the assumption that it is a normal variant is preferable, since it would tend to agree with electrocardiographic studies in which normal electrocardiograms are more often seen with cardiac disease than are abnormal electrocardiograms in the absence of heart disease.[7] Nevertheless, in individual cases the occurrence even of the otherwise normal S-type record should suggest thorough investigation of the case before dismissing it as a normal variant.

SUMMARY AND CONCLUSIONS

1. Electrocardiograms exhibiting prominent S waves (final inverted phase of the QRS complex measuring 25 per cent or more of the upright phase) in Leads I, II, and III were present in 84 cases of 1,850 consecutive electrocardiograms reviewed.

2. In 41 of these cases definite electrocardiographic abnormalities, such as left ventricular preponderance, right ventricular preponderance, combined right and left ventricular strain, myocardial infarction, and nonspecific abnormal patterns were found. In 8 others questionable abnormalities were present.

3. In 35 cases no other deviations from the normal pattern were observed and these were regarded as the otherwise normal S type of electrocardiogram. The criteria employed in this deduction are described. In 19 of these cases no demonstrable heart disease was present; in 3 the clinical findings were inconclusive; and in 13 there was clinical evidence of heart disease.

4. It is concluded that electrocardiograms exhibiting prominent S waves in Leads I, II, and III are more common in patients with evidence of heart disease than in normal persons in the population of an electrocardiographic laboratory. However, in an otherwise normal electrocardiogram the S type may be a normal variant, but before this decision is made the case should be thoroughly investigated.

We are grateful to Dr. L. N. Katz for his invaluable advice and criticism in this study.

ELECTROLYTE AND WATER EXCHANGE BETWEEN SKELETAL MUSCLE, "AVAILABLE (THIOCYANATE) FLUID," AND PLASMA IN THE DOG FOLLOWING THE ADMINISTRATION OF DESOXYCORTICOSTERONE ACETATE*

David M. Harkness, B.S., Edward Muntwyler, Ph.D., and Frederick R. Mautz, M.D., Cleveland, Ohio, and Robert C. Mellors, Ph.D., Baltimore, Md.

SHORTLY following the introduction of desoxycorticosterone acetate for clinical use in 1939, numerous studies appeared dealing with its therapeutic value in the treatment of Addison's disease and with its effect on electrolyte and water metabolism. These studies[1-6] revealed, among other things, that the administration of the substance to patients with Addison's disease or to animals in adrenal insufficiency leads to a retention of sodium and chloride, and to an increased excretion of potassium and phosphorus. The plasma sodium and chloride concentrations become elevated to normal, and the plasma and extracellular fluid volumes become increased. At the same time the plasma potassium becomes reduced, frequently to abnormally low levels. While many clinical studies showed favorable therapeutic results with the use of desoxycorticosterone acetate, a number of authors [1, 3, 7, 8] issued a warning that symptoms of overdosage may occur in certain patients, particularly those receiving high sodium and low potassium diets. Indications of an excessive dosage of the substance or of sodium chloride, or of both, may be found in the appearance of edema, rapid gain in weight, increase in blood pressure, and finally in signs of congestive heart failure. The administration of large doses of desoxycorticosterone acetate to normal dogs has not been found to lead to the above symptoms; however, such animals develop a syndrome resembling that of diabetes insipidus[9-11] and show periodic attacks of muscular weakness or paralysis.[10, 12]

The experiments included in this paper were undertaken for the following purposes: (1) to observe any changes of the plasma volume and "available (thiocyanate) fluid" from normal; and (2) to observe the electrolyte and water exchanges between skeletal muscle and plasma following the administration of the drug in large doses and after its discontinuance.

METHODS AND CALCULATION

Adult male dogs were used in this study and were placed on a constant diet (diet suggested by Nilson[13] and supplemented by 15 Gm. of sodium chloride

*From the Departments of Biochemistry and Surgery, School of Medicine, Western Reserve University, Cleveland.

Aided by a grant from the John and Mary R. Markle Foundation.

A preliminary report upon this work was presented before the meeting of the American Society of Biological Chemists at Boston, March, 1942 (Federation Proceedings 1: 114, 1942).

Received for publication, August 7, 1942.

and 5 Gm. of sodium citrate per day) for a period of at least seven days before the experiments were undertaken. It was customary to withhold food for eighteen to twenty-four hours before collecting the samples for analysis. Control determinations of the plasma volume and the "available (thiocyanate) fluid" were made by the direct method of Gregersen and Stewart,[14] as adapted to the photoelectric colorimeter by Gibson and Evelyn.[15] The animals then received desoxycorticosterone acetate* subcutaneously (1 mg. per kilogram of body weight daily) for a period of fourteen days, at which time the above determinations were repeated. Immediately following these determinations, blood was withdrawn under oil from the femoral artery, placed under oil in a special centrifuge tube containing heparin to prevent clotting, and centrifuged at once for the plasma analyses. Skeletal muscle (lumbar portion, sacrospinalis) was obtained under sodium pentobarbital anesthesia as quickly as possible following the collection of the blood and was sampled for the several analyses in the manner previously described.[16] The following determinations were carried out on the plasma: water, chloride, sodium and potassium; on the muscle: water, chloride, sodium, potassium, and total neutral fat. The chemical methods were the same as those employed in previous studies.[17]

The administration of the desoxycorticosterone acetate was then discontinued, and after a period of fourteen days the foregoing observations were repeated. During this interval the diet remained unchanged in three of the animals while in five others the salt supplement was changed to 3 Gm. of sodium chloride plus 10 Gm. of potassium dihydrogen phosphate daily.

The volumes of the extracellular (F) and intracellular (C) phases of muscle were calculated in the manner outlined by Hastings and Eichelberger,[18] which is based upon the assumption that all the chloride is extracellular and is present at a concentration equal to that of an ultrafiltrate of plasma. In order to approximate the volume changes produced in the extracellular and intracellular phases of 1 kilogram of original muscle, the calculations were made relative to a control series, assuming a constant solid content of the intracellular phase. The partition of sodium and potassium between the extracellular and intracellular phases of muscle was carried out by the method described by previous authors.[18, 19] The experimental values herein reported for intracellular sodium and potassium are given in terms of a kilogram of intracellular water and have been corrected to an intracellular solid content equal to that of the control mean.

RESULTS

Changes of the Plasma Volume and "Available (Thiocyanate) Fluid."— Measurements of plasma volume and "available (thiocyanate) fluid" were carried out on nine animals following the administration of desoxycorticosterone acetate and on eight animals after its discontinuance. On the basis of individual control levels, the plasma volume was found to be increased by an average of 11 per cent and to range from 1 to 33 per cent, with an increase greater than 10 per cent occurring in four instances. (The increase of plasma volume amounted, on the average, to 77 c.c., with a range of variation from 8 to 206 c.c.). Likewise the "available (thiocyanate) fluid" was found to be increased

*We are indebted to the Schering Corporation for the generous supply of crystalline desoxycorticosterone acetate in sesame oil (Cortate) which was employed for these studies.

by an average of 15 per cent and to range from 5 to 40 per cent, with an increase greater than 10 per cent occurring in five instances. (The increase of "available (thiocyanate) fluid" amounted, on the average, to 700 c.c., with a range of variation from 290 to 1,600 c.c.)

Fourteen days after the administration of the drug had been discontinued, there was found to be a persistence of the average increase of the plasma volume and, although less, of the "available (thiocyanate) fluid." Thus the plasma volume was found to be increased by an average of 16 per cent and to range from 2 to 42 per cent, with an increase greater than 10 per cent occurring in five instances. Similarly, the "available (thiocyanate) fluid" was found to be increased, on the average, by 7 per cent and to range from –5 to 21 per cent, with values greater than 10 per cent occurring in only three instances.

From these data it would appear that, although in a fairly high percentage of animals receiving large doses of desoxycorticosterone acetate the increases of plasma volume and "available (thiocyanate) fluid" may not exceed the possible experimental error, there does seem to be a definite tendency for both volumes to become elevated and in some instances to become elevated appreciably.

TABLE I

ELECTROLYTE AND WATER CONTENT OF PLASMA FROM DOGS FOLLOWING THE ADMINISTRATION OF DESOXYCORTICOSTERONE ACETATE AND AFTER ITS DISCONTINUANCE*

*Two-week periods. One milligram per kilogram of body weight of desoxycorticosterone acetate was administered daily. The numbers within the parentheses indicate the number of animals.

†High sodium and low potassium diet.

‡Low sodium and moderately high potassium diet.

Plasma Changes.—The results of the analysis of plasma are presented in Table I. By comparison with a control series[2] it will be seen that the outstanding changes encountered following the administration of desoxycorticosterone acetate were the deficits in the average levels of potassium and chloride. That there was a tendency to an elevated plasma sodium concentration was indicated by the slightly elevated average value.

Two weeks after the administration of the drug had been discontinued, the plasma sodium showed, on the average, a further increase in the three animals whose diet was left unchanged, while it fell back to the control mean in the

five animals whose salt supplement was changed to 3 Gm. of sodium chloride plus 10 Gm. of potassium dihydrogen phosphate daily. Some decrease of the average levels for both potassium and chloride was still found to be present in both groups of animals.

Attention should be called to the fact that Kuhlman, Ragan, and associates,[12] and Ferrebee, Parker, and others[10] noted an increase of the plasma sodium concentration amounting to about 4 or 5 meq. per liter and a fall of the plasma potassium of about 1 to 1.5 meq. per liter in normal dogs receiving 25 mg. of desoxycorticosterone acetate daily for periods of twenty or more days. Although the changes of the plasma sodium were less striking, the deficits of plasma potassium encountered in the present experiments are of the order noted by the above workers. It is of some interest that even though the plasma potassium tended to return to normal, the average figure was still lowered somewhat two weeks after the discontinuance of the drug despite the added daily intake of potassium.

ΔC, Gm.			-23	-59	30
ΔF, Gm.			7	30	-19

*Lumbar portion, sacrospinalis. One milligram per kilogram of body weight of desoxycorticosterone acetate was injected daily for fourteen days.

†Per 1,000 Gm. of muscle cells.

‡Per 1,000 Gm. of intracellular water, corrected to a solid content equal to that of the control. Numbers within the parentheses indicate the number of animals.

Skeletal Muscle Changes.—The results of the analysis of skeletal muscle have been presented in Tables II and III. By comparing these data with those of a control series,* it will be observed that two weeks following the administration of desoxycorticosterone acetate (Table II) there was a striking fall of skeletal muscle potassium and a gain of sodium. The muscle chloride remained unchanged while the average water content was lowered slightly.

The partition of sodium and potassium between the extracellular and intracellular compartments of skeletal muscle revealed that the "excess" sodium, which can be located in the intracellular phase, $[Na]_c$, increased from a control level of 12.7 meq., ±4.7 meq., per kilogram of intracellular water to an average figure of 35.6 meq., with a range of variation from 21 to 54 meq. Simultaneously, the average intracellular potassium per kilogram intracellular water, $[K]_c$,

*The data for plasma and skeletal muscle of the control series were reported in connection with another study.[11] These observations were carried out on a separate series of animals; however, the chemical methods and management of the animals were identical with those employed here.

fell from the control level of 145.0 meq., ±11.7 meq., to 111.2 meq., with a range of variation from 88 to 124 meq. It will be observed that, on the average, the sum of the concentrations $[Na]_c$ and $[K]_c$ become lowered by 10.9 meq., indicating that the gain of "excess" sodium did not completely compensate the loss of intracellular potassium. In this connection it will be seen that the calculations of the volume changes produced in the extracellular and intracellular phases of 1 kilogram of control muscle revealed some irregularity. However, on the basis of an average 23 Gm. decrease in the intracellular phase, ΔC, and an average amounted to a decrease of 16 Gm. per kilogram of control muscle, ΔM, consisting of an average 23 Gm. decrease in the intracellular phase, ΔC, and an average 7 Gm. increase in the extracellular phase, ΔF. Thus, despite a marked divergence from normal of the electrolyte pattern of the intracellular phase, there were, on the average, no striking changes from normal in the volume relationship between the extracellular and intracellular phases. In fact, the average volume changes encountered were in the direction of those which might be anticipated on the basis of a gain of the extracellular sodium concentration and of the "available (thiocyanate) fluid."

*Lumbar portion, sacrospinalis. Observations were made fourteen days after discontinuance of desoxycorticosterone acetate administration.

†Per 1,000 Gm. of muscle cells.

‡Per 1,000 Gm. of intracellular water, corrected to a solid content equal to that of the control. Numbers within the parentheses indicate the number of animals.

By comparing the data presented in Table III with those given in Table II, it will be observed that a marked deviation from normal of the skeletal muscle sodium and potassium content was found to persist in the animals studied two weeks after the administration of the drug had been discontinued. The partition of sodium and potassium between the extracellular and intracellular compartments revealed, on the average, no tendency of the intracellular concentrations of these two cations to return to normal levels in the three animals which were permitted to continue on the diet high in sodium and low in potassium. However, in the case of the five animals which received a daily salt supplement of 3 Gm. of sodium chloride plus 10 Gm. of potassium dihydrogen phosphate during the period of drug discontinuance, a tendency for the intracellular concentrations of sodium and potassium to return to normal was noted. Thus in the latter animals

the average intracellular sodium, $[Na]_c$, was 9.7 meq. lower, and the average intracellular potassium, $[K]_c$, was 8.4 meq. higher than the average levels observed after the administration of the drug. It will be observed that as was the case with the muscles of the animals examined after the administration of the desoxycorticosterone acetate, the calculations of the volume changes produced in the extracellular and intracellular phases of 1 kilogram of control muscle revealed, on the average, no changes from normal which could not be anticipated on the basis of the extracellular sodium concentration and the "available (thiocyanate) fluid."

DISCUSSION

At the time the present experiments were being brought to a conclusion, the report by Ferrebee, Parker, Carnes, Gerity, Atchley, and Loeb[10] appeared, calling attention to the fact that normal dogs receiving daily injections of 25 mg. of desoxycorticosterone acetate develop muscular weakness and a syndrome resembling diabetes insipidus. It was pointed out, further, that there were attacks of paralysis associated with a partial replacement of the intracellular potassium of the skeletal muscles by sodium. In respect to the distortion from normal, the changes of intracellular sodium and potassium of skeletal muscle encountered in the present study are in complete harmony with those reported by the aforementioned workers. Even though smaller doses were employed in the present experiments, two of the ten dogs exhibited paralysis while receiving the drug. Interestingly enough, these two animals also showed the greatest losses of intracellular potassium and gains of intracellular sodium, the figures for $[K]_c$ being 87.7 and 96.0 meq., and those for $[Na]_c$ being 54.4 and 47.4 meq. per kilogram of intracellular water, respectively.

SUMMARY

Changes of the plasma volume, the "available (thiocyanate) fluid," and the electrolyte and water content of plasma and skeletal muscle were observed in normal dogs following the daily injection (1 mg. per kilogram of body weight) of desoxycorticosterone acetate for a period of two weeks and two weeks after the administration of the drug had been discontinued. The pertinent findings may be summarized as follows:

1. Normal dogs maintained on a high sodium-low potassium diet exhibited a tendency for both the plasma volume and the "available (thiocyanate) fluid" to become increased while receiving the drug for a period of two weeks. In many instances the increases of plasma volume and "available (thiocyanate) fluid" did not exceed the possible experimental error. However, not infrequently both volumes were found to be elevated appreciably.

2. Two weeks after the administration of the drug the animals showed, on the average, a fall of the plasma potassium and chloride concentrations and a tendency toward an elevated plasma sodium concentration. At the same time there was a striking reduction of the skeletal muscle potassium content, a gain of sodium, and no change of the skeletal muscle chloride. On the average, the loss of intracellular potassium was not completely compensated by a gain of the sodium which could be located in the intracellular phase.

3. The animals which were studied two weeks after the administration of the drug had been discontinued continued to show a marked reduction of the skeletal

muscle potassium and elevation of sodium. While there was no tendency for the intracellular concentrations of these two cations to return to normal levels in animals maintained on a high sodium-low potassium diet during this period, there was, on the average, such a tendency in the animals receiving a lowered sodium and increased potassium intake.

4. Despite the marked divergence of the electrolyte pattern of the intracellular phase from the normal, there were, on the average, no striking changes from normal in the volume relationship between the extracellular and intracellular phases.

LABORATORY METHODS

GENERAL

USE OF SODIUM DESOXYCHOLATE-LYSED ANTIGEN FOR THE PRODUCTION OF PNEUMOCOCCUS ANTISERUM*

Herman A. Iverson, M.D., and Loring W. Pratt, A.B.
Baltimore, Md.

THE production of antibodies against pneumococci by the use of lysates of pneumococci has been demonstrated by a number of investigators. Meyer,[1] and Meyer and Sukneff,[2] used a sodium taurocholate lysate of type I pneumococci to immunize rabbits and mice. Pneumococci treated with soaps (sodium ricinoleate) were used by Larson and Nelson[3] and by Larson[4] for prophylaxis in man and to produce a therapeutic antiserum. Pneumococci treated with bile salts were used as antigens by some workers.[5] White,[6] summarizing previous work, says: "Filtrates from fluid cultures and watery or saline extracts of pneumococci, representing as they do only a part of the antigenic components of the pneumococcal cell, are more limited in immunizing properties than the entire cell," and further, "while pneumococci treated with bile salts may induce immunity in mice and rabbits, and presumably in other animals, the immunity is of low order and is lacking in type specificity."

Our experiments were made with antigens prepared in three ways: 1. *Heat-killed whole cultures* of young virulent strains of type I pneumococci were made into antigens according to the method of the Massachusetts Antitoxin and Vaccine Laboratory (quoted by White). 2. *Lysate antigens,* made from sixteen-hour broth cultures of the same strains, washed with salt solution, and diluted with salt solution until the turbidity of the suspension corresponded to tube 3 of a barium sulfate standard.[8] The suspension was then lysed by adding 2 drops of sodium desoxycholate solution[9] to each 8.0 c.c. of the culture suspension. 3. *Lysate antigens,* prepared as described and *passed through a Seitz filter* to remove any possibility of production of antibodies being the result of particles of the cells that failed to dissolve. All antigens were prepared fresh daily.

Some of the rabbits were given intravenous injections of antigens for twelve consecutive days; an initial injection of 0.5 c.c., increased each day by 0.5 c.c., until a maximum daily dose of 2.0 c.c. was attained. One group of rabbits was injected according to the protocol of the Massachusetts Antitoxin and Vaccine Laboratory, consisting of a total of 18 injections given over a period of twelve weeks. Other rabbits were given a total of 12 injections in series of four con-

secutive days with seven-day rest periods between series. In the above experiments no filtered-lysed antigen was used. In still another group of rabbits, however, two animals were injected with heat-killed antigen, two with lysed antigen, and two with filtered-lysed antigen. Four daily injections were given, followed by a rest period of thirty-one days and four more daily injections. All animals were bled five days after the last injection. No significant difference was obtained when the same type of antigen was used in the above methods of immunization. It would appear, therefore, that the shorter period of immunization is to be preferred.

RESULTS

The potency of the antisera was determined by means of agglutination tests, Neufeld tests, microscopic precipitin tests by the method of Schaub and Reid,[7] and mouse protection tests according to the potency (of serum) test of the National Institute of Health. The results can be summarized in Table I. They were similar in all trials except for individual variations in the rabbits.

TABLE I

TEST	HEAT-KILLED ANTIGEN	LYSED PNEUMOCOCCUS ANTIGEN	LYSED AND FILTERED ANTIGEN
Agglutination tests	Complete in 1:320 dilution	Complete in 1:320 dilution	Not done
Neufeld tests	Slight "Quellung"	Slight "Quellung"	Slight "Quellung"
Microscopic precipitin tests	Unsatisfactory	Unsatisfactory	Unsatisfactory
Mouse protection tests	Protection against as much as 10 million L.D.	Protection against as much as 1 million L.D.	Protection against as much as 1 million L.D.

DISCUSSION

The agglutination and mouse protection titers of sera from rabbits injected twelve times on consecutive days with lysate antigen compared favorably with that of sera from rabbits given a heat-killed antigen either as 18 injections over twelve weeks or 12 injections on as many days. Four lysate immunized animals gave lower titers than any of those immunized with heat-killed antigen. In a couple of instances lower titers were obtained in animals immunized with heat-killed antigen than were obtained in those giving best results with lysed antigen. Animals immunized with filtrate from lysed cultures produced as high titer serum as those injected with lysate not filtered.

The specificity of antiserum produced in rabbits by injecting sodium desoxycholate-lysed antigen is nearly equal, in these experiments, to that of antiserum produced in rabbits with heat-killed antigens.

No apparent systemic harm was done to the rabbits by the sodium desoxycholate. Local necrosis and edema occurred when the sodium desoxycholate antigens entered directly into the tissues of the rabbit.

CONCLUSIONS

1. Sera from rabbits immunized with lysate, filtered or not, freshly prepared by treating young virulent cultures of type I pneumococci with sodium desoxy-

cholate, gave specific mouse protection and showed some ability to cause agglutination and "Quellung" in specific type sera but gave no group reaction.

2. The sodium desoxycholate-lysed pneumococci produced, in a short time, in rabbits, antisera of high titer and possessing type specificity.

THE CYTOLOGY OF THE POLYMORPHONUCLEAR LEUCOCYTE IN TOXIC CONDITIONS*

Eric Ponder, M.D., D.Sc., and Ruth van Olinda Ponder, B.A.
Mineola, L. I.

FROM time to time it has been suggested that valuable information can be obtained by considering the detailed cytology of the white blood cells in infective states, altogether apart from that given by the form of the polymorph nuclei, which is the basis of the Arneth count, the polynuclear count, and their modifications. More specifically, many observers from the time of Bodkin (1892) and Ewing (1901) have been impressed by the degenerative changes in the polymorphs seen in severe toxemias, and Strumia (1936) has classified the degenerated cells into those showing "toxic granules" (Cesaris-Demil, 1908), those with clumped granules and vacuolation, and those showing "coagulation necrosis," edema, and nuclear rupture. Taking these cytological appearances along with the "nonfilamented count" (a simplified polynuclear count, the nonfilamented cells being equivalent to cells of Class I) Amidon (1939) has tried to relate the changes in white blood cell cytology to the clinical course in toxic states (appendicitis, pneumonia, etc.), but is not enthusiastic about the practicability of the procedure, nor certain of the significance of the results.

No one who examines large numbers of properly stained blood films for the purpose of making routine differential or polynuclear counts can fail to be impressed by the variations in white blood cell cytology which present themselves,

*From the Nassau Hospital, Mineola.

but the difficulty is to express what one sees in such a way as to give the various cytological appearances (toxic granulation, vacuolation, etc.) their proper weight, so that the final result is in some way related to the clinical state of the patient. As an example of the difficulty, one soon finds that it is quite unsatisfactory to give the percentage number of cells with toxic granulations as opposed to the number without them, for the division is not sufficiently distinct, and the cells with toxic granules vary greatly with respect to the degree of granulation. Similarly, an enumeration of degenerated, as opposed to undegenerated, cells does not allow for the fact that there are many degrees of degeneration. Still further difficulty results when one considers two attributes, such as toxic granulation and degeneracy, together, for a degenerate cell may or may not have toxic granules; such attempts at an all-or-none classification only lead to Amidon's conclusion that attention to these cytological details is more trouble than it is worth.

These difficulties largely disappear if one gives up trying to enumerate all-or-none characteristics (percentage of vacuolated cells, percentage of cells with toxic granules, etc.), and substitutes an estimate of the extent to which each abnormal attribute (vacuolation, toxic granulation, etc.) appears in the average cell, describing the extent by plus signs or numbers, and forming an impression of the "average cell" while examining the film for other purposes, e.g., while making a differential count or polynuclear count.* This report is concerned with the results of applying this method to several thousand blood films over about a year's time, during which the method was being tested for its practicability.

STAINING METHODS

1. *Preparation of glassware.* New, or at least unetched, slides are washed in a strong solution of Gold Dust for hours or even days, and are rinsed thoroughly and individually in hot running water. They are then dipped in 95 per cent alcohol, wiped dry with a clean towel, and stored in covered boxes. Cover slips are cleaned in the same way. One should not use cleaning solution or acid alcohol, because anomalies in the staining reaction follow.

2. *Staining.* Films are made in the usual way from fresh blood, and with properly cleaned slides it is easy to prepare thin and even films. Heparinized blood can be used if fresh, but oxalated blood should not be used. The film is allowed to dry in air, and is fixed for five minutes in methyl alcohol in a Coplin jar. The methyl alcohol must be "absolute, acetone free," and should be frequently replaced; if this is not done, anomalies in staining result. The fixed film is dried again in air before the application of the stain. Giemsa blood stain, stock solution, is diluted 1:10 with distilled water, the dilution being made just

*Osgood and Ashworth illustrate toxic neutrophiles in their *Atlas of Hematology*, Nos. 87 to 92. They describe three cytological changes in toxic conditions: basophilia of cytoplasm, the presence of vacuoles, and the presence of toxic granules. These they grade from one plus to four plus, and they say that death occurred in 100 consecutive cases in which two of these factors were graded from three to four plus. On the system of grading described in this paper, three plus and four plus are of less serious prognostic significance than on theirs. It will be noticed that their system does not include a grading of the feature "pyknotic nuclei," because this feature is not so clearly observed with Wright's stain, which Osgood and Ashworth use. They continue: "Evaluation of toxic changes is more reliable in prognosis than either the staff cell count or the ratio of neutrophiles to total polymorphs, but the use of all these criteria is worth while. Rosenthal and Sutra count the percentage of polymorphs showing toxic granules and report the result as the 'degenerative index.' We have had better results by evaluating all three toxic changes, and it is simpler to report these on a scale of one plus to four plus as one is doing the differential count." This corresponds to our experience.

before the stain is to be used; buffering is unnecessary if the water is freshly distilled. The slide, placed film-side up on a staining rack, is flooded with the diluted stain. The duration of staining is most important, and should be neither more nor less than thirty minutes, at the end of which time the film is rinsed with running distilled water for fifteen seconds, flooded with distilled water for thirty seconds, and finally tipped up on end to dry in air. The back of the slide is polished while it is still wet, and the examination of the cells is carried out with an oil-immersion objective in the usual way on the unmounted film. The slightest variation from this standard procedure will result in changes in the staining reaction, and, as a control on the staining method, one may use a film of one's own blood.

GRADING OF CYTOLOGICAL FEATURES

One hundred polymorphs are examined, as in the making of a polynuclear count, which, indeed, is done on every film, as described by Cooke and Ponder (1928). As each polymorph is seen, it is carefully examined and mentally classified as regards four features other than nuclear configuration: (1) whether the cytoplasmic granules are large, separated, and deeply staining, metachromatic or azurophile ("toxic granulation"); (2) whether the cell outline is sharp and circular, or irregular and presenting pseudopods ("ameboid"); (3) whether the cytoplasm of the cell is vacuolated ("vacuolation"); and (4) whether the nucleus shows pyknotic areas ("pyknotic nuclei"). After such a survey the observer will be able to form an opinion of the cytology of the average cell with respect to four features: toxic granulation, ameboid, vacuolation, and pyknotic nuclei. He will be able to give a somewhat arbitrary grade to each of these features, from one plus to four plus, and it is a matter of experience that he can do so with a surprising degree of certainty.

All sorts of elaborate schemes could be devised for expressing the results of the survey, but we have found it sufficient to denote the occurrence of each abnormal feature by a plus sign (from one plus to four plus), and to add the number of plus signs together, averaging the number of plus signs for the features "ameboid" and "vacuolated." The result of the survey is then represented by a figure which varies from 0 to 12, the value 0 meaning that all the abnormal cytological features are absent, and the value 12 meaning that they are each present to a maximal extent. For example, if a film shows:

Toxic granulation	+++
Ameboid	+
Vacuolation	+
Pyknotic nuclei	++

it is described as a film of grade 6. Again, if a film shows the following features:

Toxic granulations	++++
Ameboid	++
Vacuolation	++++
Pyknotic nuclei	++

it is described as a film of grade 9. A normal film is obviously one of grade 0. This method of grading the films may seem rough and arbitrary, but, nevertheless, it expresses the results of the cytological survey in a remarkably satisfactory way.

SIGNIFICANCE OF THE CYTOLOGICAL CHANGES

Considerable experience in grading polymorphs has brought out a number of points which have a bearing on the significance of the cytological changes.

1. The changes are not of an all-or-none nature, some cells showing them and some not. They affect all the cells, although some more than others, and this results in the information given by the grade being very different from that given by the polynuclear count. The figures for the various classes of the polynuclear count give the proportion of young cells (Class I) to older cells (Classes II, III, IV, and V, in order of increasing age), and a left-handed deflection shows that there has been either an increased production of young cells as a result of marrow stimulation, or an increased destruction of the older cells, or a combination of the two. This corresponds, by analogy with what occurs in a population, to an increased birth rate, an increased death rate in the older classes, or to a combination of both, and is a change which is characteristic of the population as a whole rather than of any one member in it. The grade, on the other hand, is an expression of the average state of the cell, not as regards age, but as regards cytological appearance and the processes which determine it at the moment; to extend the analogy, this would roughly correspond to the average nutrition of the individuals of the population. Whereas a change in the polynuclear count expresses a disturbance of the production-destruction steady state, a change in the grade seems to be evidence of an alteration in the *milieu* in which the cells circulate, and this produces substantially the same changes in all the cells simultaneously. An excellent example of this can be seen in cases where films are made within a few hours of an accident resulting in extensive tissue damage; e.g., compound fracture of femora, two hours after accident: 29,700 leucocytes per cubic millimeter, 81 per cent polymorphs, polynuclear mean, 1.41, grade 6.* The cells of all the polynuclear classes, from I to V, and even polycytes if they are present, show the changes in cytology, although the large number of cells of Class I are young cells just liberated from the marrow, while the cells of the higher classes must have been normal inhabitants of the blood stream at the time of the accident. Perhaps the best of all instances of the rapid development of pyknotic nuclei in the polymorphs of all the polynuclear classes is to be found in the guinea pig after the injection of nucleic acid (Curphey and Ponder, 1941); the multilobulated polymorphs (as high as Class X) all develop pyknotic nuclei within an hour of the subcutaneous injection of 1 mg. of nucleic acid per kilogram, and regain their normal appearance from four to eight hours later.

2. Deflections of the polynuclear count without anything more than the most trifling change in the grade (e.g., from 0 to 1, or from 1 to 2) occur after inhalation anesthesia (ether, ethylene, etc.) and can be discounted.

3. While a left-handed deflection of the polynuclear count is an excellent measure of the severity of an acute infection, and while a subsequent right-handed shift is a reliable indication of recovery, it is well recognized that the count tends to become stabilized at a low figure (usually 1.2 to 1.5) in chronic infections or in toxic states of long duration. Under these circumstances the

*This case may be contrasted with one of hemorrhage from the radial artery, uncomplicated by toxic manifestations: 21,000 leucocytes per cubic millimeter, 90 per cent polymorphs, polynuclear mean 1.28, grade 0.

fixed polynuclear count does not reflect small changes in the severity of the toxemia, and the grade is a far more sensitive measure of variations in the toxic state. Changes in the grade from day to day are of great prognostic value, especially if there is a definite trend, and although these changes are ultimately followed by corresponding shifts in the polynuclear count, they constitute the better guide to progress and indication of the outcome (cf. footnote,* page 317).

4. The various cytological features do not always undergo alteration simultaneously. The appearance of vacuoles, however, is so constantly accompanied by an ameboid cell outline that the abnormal properties "vacuolation" and "ameboid" can be considered as two manifestations of the same underlying change, and each given only half the weight of an abnormal attribute in determining the grade. "Pyknotic nuclei" often occur without any other abnormal cytological feature being present, and almost invariably do so when the patient becomes either dehydrated or acidotic.

5. There are certain artifacts which may lead to misinterpretations if unrecognized. The most important of these are the artifacts introduced by variations in the staining method, and it cannot be too strongly emphasized that the system of grading described here is entirely dependent on the staining methods being carried out without modification. The most frequently occurring artifacts are the following: (a) On improperly cleaned slides, and particularly on slides cleaned with acid, cleaning solution, and acid alcohol, the cytoplasm appears pink and the nuclei show pyknotic areas. (b) Methyl alcohol which is not fresh produces the same artifacts as are seen on slides cleaned with acid solutions. (c) Films made from blood kept for some hours in the refrigerator are likely to show cells which are vacuolated and ameboid. (d) Films made from oxalated blood show shrunken white blood cells, the cytology of which is very different from that of cells from fresh or heparinized blood. (e) Cells in films from patients who have been treated with sulfonamide drugs, and particularly sulfanilamide, are ameboid and vacuolated.

CLINICAL ILLUSTRATIONS

Tables I, II, and III illustrate the results of using this method of grading.

Table I shows the total white blood cell count, the polymorphs percentage, the polynuclear count mean, and the grade in patients who showed no signs of toxemia clinically. I have used the preoperative figures for 12 consecutive cases in which partial gastrectomy or colectomy was performed, since these provide a good illustration of what is found in surgical cases without toxic manifestations. Inspection of Table I shows that the grade, rather than the total white cell count, the polymorph percentage, or the mean of the polynuclear count, is the reliable indication of the absence of toxemia.

Table II gives the same data in 12 cases in which there were clinical signs of severe toxemia. Again it will be apparent that the grade is a better indication of the toxic condition than the total white blood cell count, the polymorph percentage, or the polynuclear count.

Table III shows the values for the grade in a series of miscellaneous toxic conditions (corresponding roughly to Amidon's Table IV). By "first observation" is meant the observation on admission or at the time of the acute episode,

TABLE I

	TOTAL COUNT × 10^{-3}	POLYMORPHS %	POLYNUCLEAR MEAN*	GRADE
Carcinoma of cecum	11.2	69	2.21	0
Carcinoma of rectum	9.3	54	2.20	0
Stenosing gastric ulcer	4.7	42	2.16	1
Stenosing gastric ulcer	7.4	79	2.00	0
Stenosing gastric ulcer	9.2	58	1.98	0
Carcinoma of sigmoid	6.1	74	1.78	0
Stenosing gastric ulcer	8.4	64	1.75	1
Stenosing gastric ulcer	10.2	60	1.66	1
Carcinoma of sigmoid	7.7	65	1.66	1
Endometriosis of cecum	14.3	76	1.64	2
Carcinoma of hepatic flexure	5.9	64	1.39	3
Carcinoma of pylorus	14.1	82	1.36	2

*By the polynuclear mean is meant the average number of lobes per polymorph. It is computed in a count of 100 polymorphs by multiplying the number of cells with one lobe to the nucleus by 1, the number with two lobes by 2, the number with three lobes by 3, the number with four lobes by 4, and the number with five or more lobes by 5; the figures are added together and divided by 100. The resulting figure expresses in a general sort of way, what is expressed by writing out the figures for the count in extenso. The normal polynuclear mean ranges from 2.3 to 2.7; means less than this correspond to "left-handed deflections," and the most extreme deflection (100 cells of Class I) corresponds to a mean of 1.0

TABLE II

	TOTAL COUNT × 10^{-3}	POLYMORPHS %	POLYNUCLEAR MEAN	GRADE
Toxemia of pregnancy	7.6	66	2.49	10
Pelvic inflammatory disease	8.5	60	2.24	7
*Subacute endocarditis	3.9	81	1.77	9

*Retroperitoneal hemorrhage; ruptured bladder; pneumonia	8.2	89	1.16	10

*Died.

TABLE III

	OBSERVATION FIRST	OBSERVATION FINAL	INTERVAL IN DAYS
Frostbite, both feet. Demarcation with loss of toes under conservative treatment. Uneventful recovery	3	1	21
Bullet wound of chest; hemothorax. Uneventful recovery	1	0	8
Perinephritic abscess. Drainage. Uneventful recovery	4	1	7
Volvulus of ileum. Resection with ileostomy. Slow convalescence	6	2	19
Incomplete abortion. Pelvic thrombophlebitis following curettage. Recovered	5	1	12
Ruptured appendix with peritonitis. Uneventful recovery	5	0	10
Nephrolithiasis. Operation followed by pneumothorax and collapse of right lung; pneumonitis. Recovered	8	2	20
Gangrenous appendix with peritonitis. Died on fourth day	5	10	4
Intestinal obstruction due to adhesions. Operation followed by aspiration pneumonia. Died	6	9	3
Multiple fractures; retroperitoneal hemorrhage; anuria. Died	4	12	4

and by "final observation" is meant the observation at the time of discharge or death. The interval in days is the interval between the two observations, but it ought to be pointed out that in actual practice observations are made daily, and sometimes more frequently. Table III illustrates the fact that an improvement in the grade corresponds to a good prognosis, while the abnormal cytological features become more prominent as the clinical condition becomes worse. This conclusion is borne out by an experience which now extends to an examination of several thousand blood films.*

CONCLUSIONS

1. In toxic conditions the polymorphs show a number of cytological changes, the principal ones observed with Giemsa stain being toxic granules, an ameboid outline, cytoplasmic vacuoles, and pyknotic areas in the nucleus. A simple method is described for grading the cells of a film according to the degree to which each of these abnormal appearances is developed, the grade varying from 0 for normal cells to 12 for the polymorphs seen in extremely toxic conditions.

2. The grade assigned by this method closely reflects the clinical condition of the patient, much more so than the total white blood cell count, the polymorph percentage, the "degenerative index" (which it replaces), or even the polynuclear count. Changes in the grade taken together with changes in the polynuclear count are of real prognostic value.

*Amidon (1939) remarks that the information gained from various hematological methods of examination must be balanced against the time, effort, and equipment required, and concludes that the determination of the degenerative index, in particular, is impracticable because it requires a degree of training and technical skill not to be expected of the average hospital technician. In our experience there is no greater difficulty in grading white blood cells than there is in doing a differential white blood cell count on abnormal blood or in doing a polynuclear count. Even the beginner is not likely to have much difficulty if he once realizes that it is essential to standardize the staining method.

IS THE MAINTAINED SEDIMENTATION RATE SPECIFIC FOR MALIGNANCY?*

JULIUS J. HERTZ, M.D., AND SEYMOUR H. RINZLER, M.D.
NEW YORK, N. Y.

WITH THE TECHNICAL ASSISTANCE OF HELEN BERNSTEIN

IN 1937 Koster[1] drew attention to the fact that the sedimentation rate of erythrocytes in stored citrated blood is subject to changes; that is, that over a twenty-four-hour period the blood sedimentation rate shows a tendency to decrease. However, in certain specimens of blood the sedimentation rate remains the same throughout the twenty-four-hour period, for example, in malignant tumors and Hodgkin's disease. This observation was found to be correct in 95 per cent of 112 cases of malignant tumors and 14 cases of Hodgkin's disease. In 100 normals and 460 nonmalignant cases the rate was found to decrease steadily over a twenty-four-hour period (Table I). In 1940 Feldman[2] repeated Koster's work. His study consisted of 176 cases, of which 118 were proved malignancies and 55 were pathologic conditions other than malignancy. The percentage of positive results in the malignant cases was 95.7 per cent, and of negative results was 94.6 per cent in the nonmalignant cases. The methods of Koster and Feldman differed only in that the former used a Westergren tube and the latter used a Wintrobe tube in determining the sedimentation rate.

TABLE I (After Koster)

SEDIMENTATION RATE	DIRECT	1 HR.	2 HR.	3 HR.	4 HR.	5 HR.	6 HR.	24 HR.
Carcinoma of stomach (positive test)	17½	17	16½	17	17	19	20	17½
Ulcerative colitis (negative test)	30	27	25	26	22	16	14	3

The importance of further confirmation of such a relatively simple laboratory procedure seemed to us obvious.

METHOD

Our technique was essentially the same as described by Feldman. Two cubic centimeters of 3.8 per cent sodium citrate were placed in a dry 10 c.c. syringe and 8 c.c. of venous blood were drawn up. This mixture was used as the pooled specimen with which sedimentation rates were done directly and after one, two, three, four, and twenty-four hours. Koster and Feldman did rates for six hours the first day. We found that after four hours the tendency of the curve was established. The blood was thoroughly shaken before each

*From the Medical and Surgical Services of Beth Israel Hospital, New York City.
Received for publication, June 24, 1942.

new sedimentation rate was done so that the cells which had settled out could be thoroughly mixed with the serum. The tubes were read exactly one hour after filling. Wintrobe sedimentation tubes and a Wintrobe rack were used. Both the tube and pipettes were carefully cleaned and dried with alcohol and ether before use. The pooled specimen was placed in a refrigerator overnight, and the next day the temperature of the specimen was allowed to return to room temperature before the twenty-four-hour rate was done. Duplicate tests showed no greater variation than 2 to 3 mm. in the comparison of hourly sedimentation rates (Table II).

TABLE II

SEDIMENTATION RATE	DIRECT	1 HR.	2 HR.	3 HR.	4 HR.	24 HR.
First test	13	12	7	7	6	4
Second test	11	10	8	8	7	4

According to Koster, the criteria for a positive test (malignancy) are as follows (Table III):

TABLE III (After Koster)

SEDIMENTATION RATE	DIRECT	1 HR.	2 HR.	3 HR.	4 HR.	5 HR.	6 HR.	24 HR.
Type 1	17½	17	16½	17	17	19½	20	17½
Type 2	70	73	78	76	95	96	94	107
Type 3	30	30	35	38	39	38	36	16

Type 1: The rate of sedimentation remains at the same level throughout the twenty-four hours, or it does not vary to more than 20 per cent of the initial value.

Type 2: The rate of sedimentation markedly increases above the initial value in the course of the estimation and does not decrease to below the initial value.

Type 3: After having risen to above the initial value, the rate of sedimentation again decreases gradually, often to far below the initial value.

MATERIAL

The patients were selected from the adult medical and surgical wards of Beth Israel Hospital and from our private practice. All diagnoses of malignancy were confirmed either by roentgenogram, biopsy, surgery, or necropsy. In the majority of instances the cases were taken as consecutive admissions. In all, there were 100 patients of whom 33 had proved malignancies.

RESULTS

Our percentage accuracy for diagnosing malignancies was 54 per cent (Table IV) as compared with Koster's 95 per cent and Feldman's 95.7 per cent (Table V). Our percentage accuracy in nonmalignant cases was 72 per cent as compared with Koster's 100 per cent and Feldman's 94.6 per cent. Sedimentation tests were repeated on the majority of our false negatives two or more times.

DISCUSSION

Our results obviously do not agree with those of either Koster or Feldman. In our series of malignant cases about one-half gave false negatives. False

negatives may be attributed to hemolysis of the specimen, insufficient shaking before each sedimentation rate so that the cells and serum are not thoroughly mixed, or not allowing the twenty-four-hour specimen to come to room temperature after removing it from the refrigerator. All of these make for a slower sedimentation rate and, therefore, tend toward the negative curve. These pitfalls were carefully avoided, as shown by the fact that ten patients on whom tests were done at the same time from specimens taken by two injections showed no more than 2 to 3 mm. variation in the hourly specimens (Table II).

TABLE IV

	TOTAL NO.	WITH POSITIVE SEDIMENTATION RATE	WITH NEGATIVE SEDIMENTATION RATE	PERCENTAGE ACCURACY
Proved malignancies	33	18	15	54
Nonmalignant	67	49	18	72

TABLE V

	% POSITIVE	% NEGATIVE
Koster	95	100
Feldman	95.7	94.6
Hertz and Rinzler	54	72

According to Koster and Feldman, false positives may result from the following drugs: the sulfonamides, potassium iodide, bismuth, salvarsan, aminopyrine. We have eliminated from this series any patients who were taking any of the sulfonamides. Other drugs taken by our patients include: atropine, phenobarbital, thyroid extract, thiamine chloride, caffeine citrate, ammonium chloride, amytal, cevitamic acid, feosol, and Lugol's solution. These drugs were taken in therapeutic doses by both the true negatives and false positives, both groups being nonmalignant. Diagnoses on some of the false positives were: chronic diffuse glomerular nephritis (3 tests); calculus of the common duct (5 tests); congestive heart failure (2 tests); and lupus erythematosis (2 tests).

We, therefore, feel that this test is of no value in our experience in accurately differentiating malignant from nonmalignant disease.

SUMMARY

Sedimentation tests done serially according to the methods of Koster and Feldman on 33 patients with proved malignancies and 67 patients with pathologic conditions other than malignancy showed 54 per cent positive results in the malignant cases and 72 per cent negative results in the nonmalignant cases. We must conclude that in our hands the test is not accurate for use in the differential diagnosis between malignant and nonmalignant conditions.

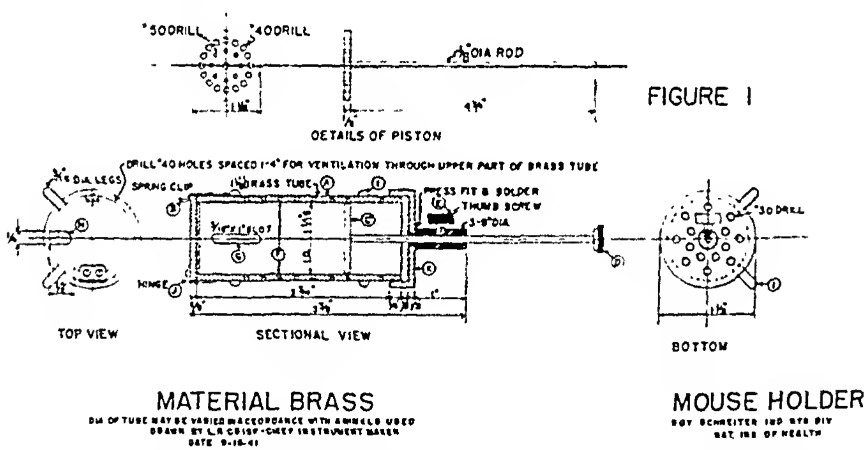
MOUSE HOLDERS FACILITATING INTRAVENOUS AND INTRAPERITONEAL INJECTIONS*

Roy Schneiter, M.S., and Lawrence R. Crisp

Although the intravenous injection of mice is a relatively simple procedure, the use of this route of inoculation is often limited because of the lack of a satisfactory apparatus for holding the animal during injection.

Very few satisfactory mouse or rat holders have ever been described. Burdon[1] described a mouse holder which consists essentially of a slitted, illuminated box on top of which is attached a wire cage for holding the animal. This holder, although it has many desirable features, appears to be somewhat cumbersome, and it is not adjustable to the length of the animal.



The apparatus described in this report was designed for simplicity and rapidity of operation and is adjustable to the length of the animal. Two types of holders have been designed (Figs. 1 and 2). The holders illustrated are made of brass tubing of suitable diameter for accommodating either large or small mice. The tube has a hinged, slotted door at the end or is hinged at the long, horizontal axis of the tube to permit the admission of the animal. A plunger for adjusting the length of the tube to the length of the animal is provided, and the animal is thus immobilized for either injection or bleeding. These holders are compact and easy to use and may be completely dismantled for cleaning and sterilization. With very little practice, mice may be readily induced to enter the holder.

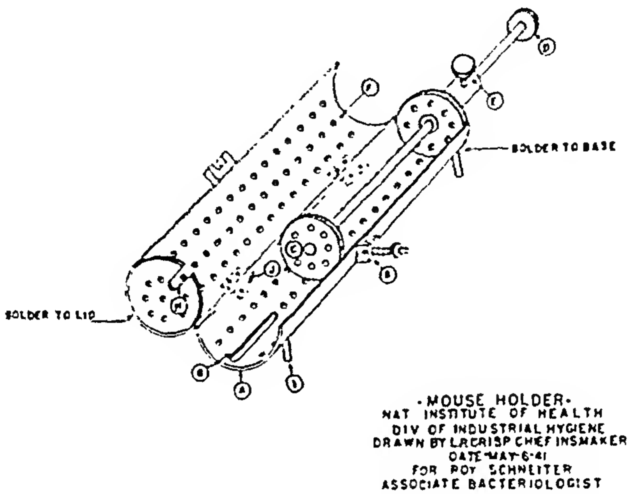
*From the Division of Industrial Hygiene, National Institute of Health, United States Public Health Service, Bethesda, Md.

Received for publication, May 23, 1942.

By a selection of brass tubing of suitable diameter, either type of holder may be constructed for work with rats.

Each type of holder has been designed with a slit to permit intraperitoneal injections. A single worker with the aid of these holders can readily make intravenous or intraperitoneal injections without assistance.

FIGURE 2



Diagrammatic sketches of the two types of holders are given in Figs. 1 and 2. The essential parts of the holders are described as follows: *A*, Brass tube 5 inches long, 1⅛ inches outside diameter, and ¹⁄₁₆ inch wall; *B*, spring or swinging latches; *C*, plunger for adjusting holder to the length of the mouse; *D*, handle and rod for control of plunger; *E*, set screw for locking plunger rod after adjustment; *F*, air holes Nos. 30, 40, 44, and 50 drills; *G*, slit for intraperitoneal injections; *H*, slot in end of tube for accommodating tail of animal; *I*, legs for support of holder; *J*, hinges; and *K*, threaded cap for cleaning the end-opening holder.

In making intravenous injections the holders may be placed on the laboratory table top or mounted in a ring stand. The animal is placed in the holder, and the plunger is adjusted to restrict movement. Tail veins may be brought into sharp relief by the application of xylol or alcohol. One-fourth, 0.5, or 1 c.c. hypodermic syringes fitted with 1 inch, No. 26 gauge needles are the most suitable for intravenous injections. The needle is most easily inserted at an angle almost parallel to the tail. We have found 0.25 c.c. is the maximum quantity of inoculum which can ordinarily be injected into the tail vein of the average mouse.

SUMMARY

Two types of holders have been described which facilitate the intravenous and intraperitoneal injection of mice and rats. These holders permit the utilization of these techniques by the individual worker, thus increasing the potential usefulness of these laboratory animals.

SPUTUM CONCENTRATION FOR THE CULTURE OF TUBERCLE BACILLUS*

M. Gerundo, M.D., Topeka, Kan.

Direct cultivation of tubercle bacillus has not yet become a routine procedure because of drawbacks in the manipulations and concentration of sputum.

The most widely used method is perhaps that with sulfuric acid. The sputum is mixed with equal amounts of 15 per cent sulfuric acid and then, is washed and centrifuged.

This method, however, has some drawbacks because it fails usually with dense and viscous sputa, containing large amounts of mucus and albumin. Large flakes of mucus escape contact with the sulfuric acid and finally cause contaminations of the cultures.

To obviate this difficulty, I have found the following method more satisfactory and also more reliable, because it produces a complete fluidification of the sputum, thus lessening the danger of contaminations.

The formula I use is a modified Jousset's liquid for inoscopy:

Pepsin	1 Gm.
Glycerin	10 c.c.
Hydrochloric acid	15 c.c.
Sodium fluoride	1 Gm.
Distilled water	1,000 c.c.

Mix equal volumes of sputum and solution and leave the mixture for four hours in the incubator at 37° C., shaking occasionally to facilitate homogenization.

At the end of this period centrifuge, wash with sterile saline several times to remove the acid, and make cultures with the sediment upon Petragnani's or Loewenstein's media, or prepare for microscopic examination.

The results are definitely superior to the sulfuric acid method. The culture method is preferable to animal inoculation, because it is less expensive, more reliable, and more rapid.

This method can be applied satisfactorily also to urine containing blood or albumin.

CHEMICAL

THE NATURE OF THE BLOOD IODINE AND ITS DETERMINATION*

SOLOMON SILVER, M.D., NEW YORK, N. Y.

HISTORICAL ASPECTS

SINCE the modest six-page contribution by Courtois[1] in 1813 in which he announced "the discovery of a new substance in seaweed," the study of iodine and its place in animal physiology has assumed ever-increasing interest and importance. In 1900 Gley and Bourcet[2] established the presence of iodine in the circulating blood and published figures that agree very closely with those accepted as normal today. The extent of these studies was limited by the fact that they required a liter of blood to complete a single analysis. In 1920 Kendall[3] reported values of about 13 gammas per 100 c.c. for whole blood in a small series. The first series of any size and the first values attempting to correlate the blood iodine level with clinical disorders of the thyroid gland was published by Veil and Sturm[4] in 1925. They reported values of 13 to 17 gammas per 100 c.c. as normal, and they found the blood iodine level to be increased in Graves' disease where their values varied from 21 to 70 gammas per 100 c.c. Veil and Sturm extended von Fellenberg's concept, which was widely and perhaps uncritically accepted, that the iodine in the blood existed in at least two forms. One form, which they called "organic," was insoluble in cold alcohol, and another, soluble in cold alcohol, they called "inorganic." In normal blood they found an average of 9 gammas per 100 c.c. "inorganic" and 5 gammas per 100 c.c. "organic" iodine. In Graves' disease they found that the increase was almost entirely in the "organic" fraction. In 1929 Lunde, Closs, and Pedersen[5] objected to the use of cold alcohol to separate the two forms of the blood iodine because, as they said, the "inorganic" component could never be extracted completely with cold alcohol and that further washings always contained iodine. They, therefore, proposed the use of hot alcohol in a Soxhlet apparatus using four volumes of alcohol to one volume of blood and extracting once for four hours. By this method the authors greatly increased the alcohol soluble or "inorganic" fraction so that normally they found from 7 to 12 gammas per 100 c.c. as "inorganic" and only 1 to 4 gammas per 100 c.c. as "organic" or remaining in the residue. Ultrafiltration was used as a means of separating the organic and inorganic fractions by Leipert[6] in 1937 and Trevorrow[7] in 1939, but their results are in conflict. The former found that from 70 to 90 per cent of the serum iodine was ultrafiltrable, whereas the latter found that absolutely no iodine passed through the ultra-

Received for publication, February 25, 1942.

filter. More recently, Salter[8] has resorted to protein precipitation by heat and dilute acid and differentiates between the iodine fixed to the coagulum and that which can be recovered in the filtrate. He refers to the former as "protein" iodine and to the latter as "inorganic." He admits, however, that his cannot be used if iodides have been administered and that his method gives false values for the "protein iodine" fraction if iodide is added to plasma in vitro. It is obvious that methods which fail to eliminate ingested iodide have markedly restricted application.

The purpose of this study is to demonstrate the absence of true inorganic iodine in normal blood and to show that all the normally occurring iodine is bound to the plasma proteins. In addition, a method (dialysis) is presented which permits the determination of "protein bound" or nondialyzable iodine in the presence of inorganic iodine.

METHODS

The analyses were carried out by the Matthews[9] modification of the Leipert method with the following minor variations:

1. The final oxidation to iodate was carried out in a small volume, using bromine vapor after the solution had been rendered just acid to methyl orange with phosphoric acid. Bromine was removed by boiling.
2. N/1,000 thiosulfate was used instead of N/5,000.
3. Sulfite was not used in the receiver.

This method is accurate to 5 per cent in the range of these experiments and recoveries of added iodine compounds are complete.

Duplicate determinations were done in every case. If the results did not check, new sets of duplicate determinations were set up.

The blank for the method is less than 0.05 gamma iodine per determination.

Dialyses were carried out in cellophane casings made by the Visking Company, and the duration of each dialysis was seventy-two hours in running water. Tap water can be used for dialysis if suitable correction is made for the iodine content of the water which enters the sac during dialysis.

EXPERIMENTAL

The entire question of "organic" and "inorganic" iodine in normal blood was reopened by Trevorrow, who reported that she could extract all the iodine in normal blood by ethyl alcohol. If this is true, it is obvious that there can be no distinction between "inorganic" and "organic" fractions based upon alcohol solubility. We have been able to confirm her studies and have found that all the blood iodine can be extracted with either hot or cold alcohol, provided enough of the solvent is used and the extraction is carried on long enough. The extractions with cold alcohol were carried out in stoppered flasks in a shaking machine, and those with hot alcohol were carried out in a flask under a reflux condenser and also in a Soxhlet apparatus adding the blood to the extraction thimble after the proteins had been precipitated by the alcohol.

It is clear from these experiments and the studies of Trevorrow that no reliance can be placed upon so-called "organic" fractions of blood iodine based upon alcohol solubility. It is probable that individual workers have

obtained relatively constant fractions because they kept the conditions of their extractions constant and, therefore, extracted a fairly constant proportion of the total blood iodine. This may also explain the variations in the ratio of "inorganic" to "organic" iodine from 3 to 1, as reported by Lunde and Closs[5] (or even 5 to 1) to 2 to 3, as reported by Perkin.[10] It is significant that the authors who obtained the highest "inorganic" fractions used hot alcohol in their extraction procedures.

It was clear to us that we could not use alcohol as a solvent to obtain significant partition values for the blood iodine or to differentiate between normal circulating iodine and ingested iodine. It occurred to us, as it had to Gley and Bourcet forty years ago, that the normally circulating iodine might be bound to protein and, therefore, resistant to dialysis. This proved to be the case as is shown in Table II.

It can be seen from these experiments that all the iodine that circulates normally or in Graves' disease is in a form that resists dialysis and is, therefore, fixed to a large molecule, probably protein.

DISTRIBUTION OF BLOOD IODINE IN CELLS AND PLASMA

There is no agreement in the literature regarding the proportion of the normally circulating blood iodine that exists in the red blood cells as compared with the concentration in the plasma. In 1900 Gley and Bourcet said that the red blood cells contained no iodine whatsoever. In 1940 Salter[11] indicated that

he thought there was as much iodine in the cells as in the plasma; he stated that in a euthyroid person the total blood iodine was 6 gammas per 100 c.c., the plasma iodine was 6 gammas per 100 c.c., and the iodine contained in the red blood cells was also 6 gammas per 100 c.c. Such values imply equal iodine distribution between plasma and cells when the hematocrit reading is 50 per cent. Trevorrow stated that "whole blood and plasma showed a distribution of the total iodine in proportion to the water content of the plasma and cells." Klassen, Bierbaum, and Curtis[12] found that the red blood cells account for only 5 per cent of the blood iodine and even this must be viewed with some reserve because the methods used have an error as large as 5 per cent.

Our studies with red blood cells washed four times with iodine-free 0.9 per cent sodium chloride solution reveal only traces of iodine. In our opinion the red blood cells are free of any significant quantity of iodine detectable by present methods. This is easily understood because all the blood iodine is in the plasma in a nondiffusible form, and the surface of the red blood cells probably acts as a semipermeable membrane, preventing the iodized molecule from entering.

It remained for us to demonstrate that iodide added to blood in vitro or ingested in vivo could be differentiated from the normally circulating blood iodine. For this separation the procedure of dialysis again proved completely satisfactory.

The representative data in tables demonstrate that the procedure of dialysis is a satisfactory answer to the problem of differentiating between normally circulating blood iodine and iodine ingested in the form of iodide.

In the course of these studies it became evident that certain organic iodine compounds reacted in a manner very different from the behavior of the inorganic salts of iodine. When these compounds were added to whole blood, plasma, or other protein solutions, they could not be removed quantitatively by dialysis, although they are easily dialyzable in aqueous solution. Apparently new compounds were formed with the proteins and these compounds resisted dialysis. A large series of organic iodine compounds was studied using different protein solutions. The quantitative aspects of the reaction are not simple, but the proportion of the added iodine compound rendered nondialyzable varied with the protein, the organically bound iodine compound, and the relative amounts of each employed. The following substances behaved in a qualitatively similar fashion: thyroxine, diiodotyrosine, tetraiodophenolphthalein, diodrast, and hippuran.

SUMMARY

1. All the normally circulating blood iodine can be extracted with ethyl alcohol if proper precautions are taken. The distinction between organic and inorganic blood iodine based upon alcohol solubility is without foundation, and significant quantities of "inorganic" iodine in normal blood exist only as an artifact of chemical manipulations.

2. Practically all the normally circulating blood iodine is in the plasma. The amount present in washed red blood cells is too low to be determined by present methods.

3. All the normally circulating blood iodine or that circulating in Graves' disease is in a form which resists dialysis and is probably bound to protein.

4. Dialysis removed from the blood all iodine added or ingested in the form of iodide and can be used to remove ingested iodide known to the observer or unsuspected by him.

5. Dialysis does not remove completely added or ingested iodine in the form of diiodotyrosine or thyroxine.

UREA SPOT TEST FOR THE DETECTION OF NITROGEN RETENTION*

Hans Norbert Naumann, M.D., Milton Plotz, M.D., F.A.C.P., and Nathaniel E. Reich, M.D., Brooklyn, N. Y.

In 1922 Weltmann and Barrenscheen[5] called attention to the yellow reaction of urea with Ehrlich's para-dimethylaminobenzaldehyde reagent and suggested its use as a simple clinical test for nitrogen retention. This test was recommended some years later by Hunt.[3] In 1934 Patterson[7] described a spot test based on Weltmann and Barrenscheen's color reaction. The test was performed by mixing a few drops of blood with an Ehrlich reagent containing trichloroacetic acid in a small test tube and pouring the mixture on filter paper. A yellowish coloration of the moist area around the dark brown protein precipitate in the center indicated a substantial increase of blood urea. Krieger in 1934[4] confirmed the reliability of the test and introduced color standards of picric acid on filter paper. However, Heggie[2] in 1938. after investigating Patterson's spot test with blood specimens of known urea concentration, arrived at the conclusion that the method is inadequate not only for high concentrations, but also for the most important clinical range of 50 to 100 mg. per 100 c.c. urea. The potential usefulness of such a test as an emergency bedside procedure, if reliable, stimulated the present investigation and led to a satisfactory modification of the original Patterson test.

We agree with Heggie in concluding that Patterson's urea spot test in its original form is not adequate because under the conditions of the test even a considerable elevation of blood urea cannot be detected with any degree of accuracy. As long as the spot on the filter paper is still wet, it is impossible to see a definite yellow coloration, except perhaps in very high concentrations. In the course of drying the yellow color becomes gradually more distinct, but so does the color of the reagent itself. It is difficult, therefore, to note whether the yellow color is due to the urea reaction or to the color of the reagent.

*From the Department of Medicine, Long Island College of Medicine, and the Kings County Hospital (Long Island College of Medicine Division), service of Dr. Carl H. Greene.
Received for publication, May 22, 1942.

From these findings two immediate objectives of our investigation were clearly indicated:

1. Inasmuch as the yellow color reaction becomes distinct after drying, a method of drying had to be found which would give a clear end point.
2. The error due to the yellow color of the reagent had to be eliminated.

MODIFICATION OF THE UREA SPOT TEST

1. *Drying.* Experiments showed that it is not necessary to dry the filter paper for many hours (as advocated by Patterson and Krieger). It may be dried conveniently over any source of heat, provided the heat is applied equally to the entire spot. It is essential not to have the spot in direct contact with the source of heat, but at some distance from it. A bridge or desk lamp may be used as the source of heat or, better still, the filter paper may be allowed to rest on a steam radiator for several minutes while the doctor or technician is free to engage in other work.

2. *Elimination of yellow color of the reagent.* On the assumption that the yellow color of the reagent might be due to various degrees of purity, different preparations of p-dimethylaminobenzaldehyde were examined.* The Eastman drug gives a slightly more intense, yellow coloration than the English preparation. Therefore, only the Eastman p-dimethylaminobenzaldehyde was used.

It was found, in addition, that the solvents and the method of preparation are of importance. For example, alcoholic solutions increase the yellow color of the reagent considerably. It was also important not to use an excess of the reagent. The reagent finally was prepared as follows:

P-dimethylaminobenzaldehyde "Kodak"	0.5 Gm.
Trichloroacetic acid	100.0 Gm.
Distilled water up to	100.0 c.c.

The reagent should be kept for convenience in a dropper bottle.

The p-dimethylaminobenzaldehyde dissolves easily in a concentrated trichloroacetic acid, producing a slightly yellow color. A drop of this reagent on filter paper dried for ten to fifteen minutes on a hot surface gives a pinkish to grayish spot, contrasting satisfactorily with the yellow reaction of the urea. Only on prolonged heating or after the paper is kept for many hours does the spot of dry reagent turn yellow.

In order to eliminate further any possibility of error due to the coloration of the reagent, it was found expedient to place the blood to be tested in the middle of a wet spot of reagent instead of mixing blood and reagent before applying the mixture to filter paper. This technique is sufficient to precipitate most of the blood proteins in a small drop and allows a clear differentiation between the yellow zone surrounding the dark brown spot of blood proteins from the outer pinkish to grayish zone of reagent itself. In addition, two further advantages exist. There is no necessity of using a small test tube for

*These samples were marketed by the following firms: British Drug Houses Ltd., London. Eastman Kodak Co., Inc., Rochester, N. Y. Eimer & Amend, New York. Hartman-Leddon Co., Philadelphia.

We wish to express our appreciation to the Eastman Kodak Co. for giving us a sample of their preparation.

mixing blood and reagent, and the amount of blood necessary for the test is decreased from several large drops to a single small drop, making this method a true microtechnique.

A drop of reagent is dropped on a small piece of filter paper. The finger is punctured in the usual manner for obtaining blood counts, and a small drop is allowed to come into contact with the moist area of the paper. The paper is dried, as described before, and is read after several minutes. A small spot of dark brown coagulated blood protein is seen in the center surrounded by a narrow yellow zone produced by the urea reaction and a pinkish-gray outer zone caused by the color of the reagent itself. The test is improved greatly in accuracy by turning the paper over and reading the result on the opposite side.* The intensity of the color reaction may be graded from 0 to 4 plus. It is wise at first to obtain a control reaction with normal blood, but those who have worked with this test soon found that a control was unnecessary. If the test is used infrequently, it is well to use a control.

INTERPRETATION OF THE TEST

The test as described is sensitive enough to show a weak yellowish zone in normal blood. Comparatively small increases of urea nitrogen up to 25 mg. per 100 c.c. (about 50 mg. per 100 c.c. urea) can be detected by comparison with the reaction of normal blood, provided the conditions of the test (amount of wet reagent, surface of blood in contact with liquid reagent, and equal heating of both spots) are kept reasonably constant. The test is not a quantitative one except very roughly. Twenty to 40 mg. per 100 c.c. of urea nitrogen produced a yellow color slightly more intense than normal; 40 to 60 mg. per 100 c.c. gives a moderately intense reaction; above 60 mg. per 100 c.c. the color is very intense.

The only compounds in blood which might interfere with the urea reaction are the sulfonamides. These dyes can be considered as derivatives of sulfanilic acid which was listed as an interfering substance with Ehrlich's reagent by one of the authors (Naumann, 1938). Monto,[5] and more recently, Churg and Lehr[1] described a quantitative determination of sulfonamides in blood based on the yellow color reaction with Ehrlich's reagent. The urea spot test as described may also be used for the detection of the sulfa drugs in blood if only a rough estimate is required. Further investigation along these lines is now under way. While conditions with marked nitrogen retention will as a rule not be those in which sulfonamide treatment may be expected, it is well to keep this possibility in mind in those cases where treatment prior to the test is unknown.

SUMMARY

1. A simple urea spot test for the detection of nitrogen retention is described, based on the yellow color reaction of urea with Ehrlich's aldehyde reagent.

2. The test, requiring a specially prepared reagent, filter paper, and a heat source, can be completed in ten minutes.

3. The sensitivity of the test is sufficient to detect slight, moderate, and marked increase of blood urea.

*Noted by Dr. Kwascevska.

4. The urea spot test may also be used for the detection and rough estimation of sulfonamides in blood which give a similar yellow color reaction. The possible interference of urea and sulfonamides with each other is pointed out.

THE TRYPTOPHAN TEST IN GENERAL PARESIS*

M. J. Madonick, M.D., and J. Lissman, M.D.
New York, N. Y.

WE BECAME interested in the tryptophan test in general paresis as a result of our experience with a case of this disease on the wards of the Morrisania City Hospital in which the reaction was positive. A further evaluation of this test in syphilis was then undertaken and it was performed on the spinal fluids of 133 paretic persons. Cases were classified as paresis in which positive blood and spinal serology and the mental picture of paresis were all present. Because of the clinical features and positive serology both in blood and spinal fluid, three cases which did not have the typical paretic gold curve were considered as cases of paresis. In addition, the spinal fluids of several cases of taboparesis, latent syphilis, meningovascular or cerebral syphilis, and nonneurological syphilis, were studied. As a control series the fluids of 102 cases of alcoholism, the major psychoses and general medical conditions were examined. Fluids from patients with a history of syphilis or with a positive serology were excluded from this control group.

The technique of the test employed was that described by Lichtenberg[19] and Aiello.[1] It is essential that the spinal fluid be clear; we found, as have other workers,[2, 4, 19, 28] that xanthochromic, hemorrhagic, and purulent fluids gave "false positive" reactions.

Table I indicates the distribution of our cases. One hundred and nine, or 82 per cent, of the 133 paretic fluids gave a positive reaction. In the control

Received for publication, June 4, 1942.

series only two positive responses were obtained; one was in a case of cerebral arteriosclerosis and one in a mild rheumatic fever. We had three persons with multiple sclerosis with paretic gold curves who gave negative responses.

TABLE I

DIAGNOSIS	TOTAL NO. CASES	GOLD CURVE	NO. CASES	TRYPTOPHAN POSITIVE	TRYPTOPHAN NEGATIVE	PER CENT POSITIVE

Psychosis with organic brain disease	1	Syphilitic	1	0	1	0

The positive response in the cerebrospinal fluid to the tryptophan test depends upon the presence of the amino acid with the same name. Riebeling[24] states that no tryptophan is found in the normal spinal fluid. This substance, according to Mouriz,[21] is normally present in the cerebrospinal fluid up to 1 mg. per 100 c.c. Jequier and Roten[17] by adding tryptophan to normal spinal fluids which gave no response to the test found that if there is less than 0.0001 Gm. of this substance in the testing fluid the result is negative. At this level a faint ring is seen. Brugi[7] found that one part of tryptophan to 10,000 parts of diluent resulted in a positive reaction.

Boltz[6] studied the spinal fluid by the test which bears his name. Grossman[13] and Harris[15] believed the test was due to cholesterol, although Boltz was uncertain as to the chemical basis for the reaction. Later authors, Riebeling, Blix and Backlin[3] and Walker and Sleeper,[31] state that this is a test for tryptophan. Table II indicates the results obtained by Boltz and other investigators employing his test or modification of it.

In the report of Steele and Nicole,[29] six of the positive cases had a syphilitic gold curve; the remainder, including the negative responses, were in cases with a paretic gold curve. They stated that 8 per cent of neurosyphilitics give a positive result, although they are not true cases of paresis. Greenfield and Carmichael[11] were of the opinion that there was no relationship between changes in the colloidal gold curve and the test. All Thomas'[30] cases of paresis had a paretic gold curve.

TABLE II

TEST	AUTHOR	CASES	TRACES	POSITIVE	NEGATIVE	PER CENT POSITIVE
Boltz	Boltz[6]	22 paresis		22	0	100
		2 taboparesis		1	1	50
		6 tabes		0	6	0
		10 psychosis with cerebral arteriosclerosis		3	7	30

	Baxter[2]	3 paresis		0	3	0

A positive tryptophan test has been considered by many writers to be specific for tuberculous meningitis.[1, 5, 8, 12, 14, 19, 23, 25, 27, 28] Spillane,[28] accepting the work of Fildes and Knight,[10] on the ability of the tubercle bacilli to synthesize their own tryptophan in vitro on media lacking this amino acid, believes that a positive test is, therefore, due to the presence of the tubercle bacillus. Boltz and Grossman,[13] interested in this test in syphilis, felt that it was an index of the destruction by the *Treponema pallidum* upon the tissues of the central nervous system. Massazza[20] thought that it was due only to the breakdown of protein. Mouriz and Piotrowski[22] believed that tryptophan was

increased in processes in which there is destruction of cells in the central nervous system. A similar view is offered by Kraus and Mezey.[15] The last-mentioned authors obtained a positive tryptophan test only in cases where other pathologic findings were present in the fluid, especially an elevated colloidal gold curve. They were of the opinion that tryptophan, though it is not the sole factor, may be one of the agents responsible for the gold curve. In our series we obtained more positive tryptophan tests in syphilitic fluids with a paretic gold curve than without one. Though this relationship is not strictly parallel, we have found many more positive tryptophan tests in syphilitic fluid with a paretic gold curve than without one. This would explain its highest incidence in paresis. On the other hand, in cases with paretic gold curves but no syphilis, as in multiple sclerosis, the test has been negative. This convinces us that more than one factor is present in syphilitic spinal fluid to account for the colloidal gold curve and the tryptophan reaction. Perhaps the greater destruction of parenchymatous nerve tissue in paresis than in the other forms of syphilis results in a greater likelihood of the simultaneous production of the factors responsible for the tryptophan reaction and the colloidal gold curve.

Greenfield and Carmichael found negative results to the test even in cases with total protein up to 1 per cent. Baxter[2] reported negative tryptophan tests in fluids showing an increased cell count and positive Pandy. Brugi and Herbert[16] believed the results paralleled the increase in albumin content and obtained positive responses in fluids in which the albumin was greater than 30 mg. per 100 c.c. Steele and Nicole, and Duncan[9] found a close correlation between the globulin and the Boltz test, and in none of their cases was the result negative when the globulin was positive. Piotrowski's work disclosed no association between the globulin content and a positive Boltz reaction. Walker and Sleeper demonstrated a varying intensity of response with the amount of protein in the spinal fluid but stated that the relationship is not a direct one. In our series of the 18 cases in which the quantitative protein was 50 mg. per 100 c.c. or over, five with figures of 100, 50, 119, 50, and 110 mg. per 100 c.c., gave a negative tryptophan reaction. The remainder in this series were positive.

Kraus and Mezey included two malaria treated cases; one with paresis gave a negative test, the other with tabes gave a positive tryptophan test. Harris found in malaria-treated cases that, although the Wassermann reaction had in most instances become less strongly positive, the Boltz test showed no change. Steele and Nicole state that the Boltz test was altered in about half the malarial treated cases, if considerable alteration from the original paretic gold curve had occurred. Riebeling, on the other hand, thought that the results were more positive in persons with general paresis who were treated, than in those not treated. Three of the five with paresis, in our series, who had received malaria therapy six weeks to four years prior to the examination of the fluid, gave positive tryptophan reactions. We feel that our series of cases treated with malaria or chemotherapy is too small to warrant any definite conclusion in regard to the effect of the therapy on the tryptophan response.

Kraus and Mezey found a negative test in old standing neurosyphilis or in cases that had no signs of parenchymatous involvement. Schreus and Willms[26]

noted an increase in the reaction with the passing of time. They found the Boltz reaction positive in only 26 per cent of 37 cases of less than two years' duration, and in 56 per cent of 72 cases of more than two years' duration.

CONCLUSIONS

1. A total of 109, or 82 per cent, of 133 paretic fluids gave a positive tryptophan response. It was positive in 3 (100 per cent) cases of taboparesis, negative in 4 (100 per cent) cases of tabes, and positive in 5 of 13 or 46 per cent of cases of psychosis with meningovascular or cerebral syphilis.

2. The test is most often positive in cases of syphilis with a paretic gold curve, but does not occur in other diseases as multiple sclerosis where a paretic gold curve but no syphilis is found.

3. The test is not necessarily dependent upon a quantitative increase in the total protein of the spinal fluid.

4. In a control series of 102 cases in which there was no positive serology or history of syphilis, it was positive in only 2 cases, in one of cerebral arteriosclerosis, and in one of rheumatic fever.

5. From the literature we have tabulated the results of the Boltz and Riebeling tests which are probably dependent upon the tryptophan in the spinal fluid.

6. The spinal fluid must be clear because hemorrhagic, xanthochromic, or purulent fluids give false positive reactions.

We thank A. Wolfson, B.S., chemist at the Morrisania City Hospital, for aid in the examination of the spinal fluids.

EFFECTS OF DESICCATION PROCEDURES ON THE CHEMICAL COMPOSITION OF FECES, URINE, AND MILK*

D. Maxwell Teague, M.S., Harry Galbraith, M.S., Frances Cope Hummel, M.S., Harold H. Williams, Ph.D., and Icie G. Macy, Ph.D.
Detroit, Mich.

THE art and science of dehydration have been practiced from the earliest times of mankind, for the sake of either concentration or preservation. In some types of chemical work it is desirable not only to concentrate and to preserve a given mixture or substance, but also to determine quantitatively the amount of water contained therein. The method of choice in the removal of water depends upon the completeness of desiccation desired and upon the chemical or physical alterations that may occur as the material is being dried.

Food and other biological products may be concentrated and preserved, or their water content may be studied by dehydrating with heat, at atmospheric or under reduced pressure. The loss in weight that takes place during the dehydration process, before constant weight is reached, is generally assumed to be due, primarily, to the vaporization of water. Drying at temperatures of 70° C. and upward to that of boiling water, however, may result in the volatilization of essential oils,[1] loss of nitrogen,[1-3] decomposition of fats and carbohyates[4-6] and, in some cases, the removal of water may be extremely time-

*From the Research Laboratory of the Children's Fund of Michigan, Detroit.
Some of the data included in this paper were presented before the Biological Division of the American Chemical Society, at the One-Hundredth Meeting of the Society, Detroit, Mich., September 9 to 13, 1940.
Received for publication, June 10, 1942.

consuming. After protein-containing substance has been dried to constant weight, the final product may still contain from 2 to 7 per cent water.[7, 8] The use of temperatures of 100° to 110° C. for dehydration may be accompanied not only by a loss of volatile substances but also by a gain in weight from oxidation of fats and carbohydrates.[1, 6]

Some of the difficulties in the removal of water may be obviated by drying at lower temperatures (50° to 70° C.) in an inert atmosphere of nitrogen or carbon dioxide under partial pressure, if special equipment is available for this purpose. If heating must be avoided, the classic method of drying at room temperature in a partial vacuum over a desiccant may be used—a method which is tedious, time-consuming, and impractical where large volumes of water are to be removed in a short time. For rapid determination of the moisture content of biological material, reflux distillation with xylene or toluene may be applied with a high degree of efficiency and accuracy.[9, 10] This latter method has no application in the preservation or concentration of foods for edible purposes, however, nor is it practical in connection with certain types of organic analyses.

In continuous metabolic balance experiments over many days, with several subjects, the number of specimens of foods, urine, and feces involved precludes chemical analysis of all samples immediately following collection. Indeed, under the usual circumstances of staff limitation, it is not practical even to attempt all the analyses concurrent with the collections. These conditions have constantly pointed out the need for procedures by which biological specimens may be preserved for future analysis in a state chemically equivalent to that existing at the time of collection. Increasing knowledge of physiologic processes and wider recognition of the great stability of biological substances in the dry state have emphasized the necessity for a more practical method of desiccation, for preservation with less danger of denaturation than the procedures previously mentioned.[11]

Although removal of water vapor from frozen specimens by means of a chemical desiccant was used at the beginning of the century, only recently has the cryochem process ("desiccation *in vacuo* from the frozen state by means of chemicals"[12]) been developed to a high degree of refinement. This process offers a rapid and safe procedure which permits the preservation of biological material in an undenatured form for long periods of time, provided the samples are properly stored. The purpose of this paper is to point out the advantages of the cryochem procedure in accumulating biological materials for future analysis, and to demonstrate how other methods of desiccation may alter the chemical composition of the same materials. The illustrations given portray the influence of different methods of dehydration upon distribution of free fatty acids and soaps in the feces and the total fat and nitrogen contents of feces, urine, and milk. The fecal fat excretion and its partition in the feces of normal children, determined on cryochem-desiccated feces, is reported in another paper.[13]

FECAL FAT

Fecal material is much more conveniently handled and accurately sampled for analyses in the dry state, when it can be pulverized and thoroughly mixed.

In determining the total lipid content of feces, whether the wet or dried stool material is used is of no consequence as far as the results are concerned, since most methods depend on primary saponification of the material. However, in the fecal fat partition it has been claimed[16, 17] that analyses on dried stools are inaccurate and that the lipid partition should be carried out only on the wet material. Tidwell and Holt[15] have shown, in a comparison of the fat partitions on wet and dry fecal samples, that there was no significant alteration in the fecal fat distribution when feces were dried at room temperature in air. In handling a large number of fecal samples over a period of time, it is impractical to attempt desiccation of them at room temperature in air. The usual procedure has been to dry feces under alcohol in a forced draught oven, maintaining a temperature below 70° C.

TABLE I

EFFECT OF DRYING METHOD UPON FAT COMPOSITION OF FECES

CONSTITUENT*	METHOD OF DRYING SAMPLE	MG. PER GM. DRIED FECES		CRITICAL RATIO	ANALYSIS OF VARIANCE	
		MEAN ± SE_M	SD ± SE_{SD}		F	F^1
Free fatty acid	Oven	42.86 ± 2.03	7.60 ± 1.44	13.61	190	9.07
	Cryochem	14.28 ± 0.55	2.06 ± 0.39			
Soap	Oven	54.64 ± 6.10	22.81 ± 4.31	3.05	61	9.07
	Cryochem	81.86 ± 6.50	24.34 ± 4.60			
Free fatty acid plus soap	Oven	97.50 ± 6.52	24.39 ± 4.61	0.14	0.19	9.07
	Cryochem	96.14 ± 6.69	25.05 ± 4.73			

*The fat constituents were determined on the two types of dried preparation from each of 14 samples.

Corresponding samples of the feces from a group of normal children* were oven and cryochem dried. Table I compares the results of free fatty acid and soap analyses of the two types of material. The average amounts of free fatty acids per gram of dried feces were 43 mg. for the oven-dried samples and 14 mg. for the cryochem-dried; the average soap contents were 55 and 82 mg. per gram, respectively. That real differences existed for both the free fatty acid and soap determinations between the values obtained upon the samples prepared in the two ways, is shown by the critical ratios and the Analysis of Variance[15] results. The conclusion apparent from the results is that during the process of drying in the oven, a portion of the soaps was hydrolyzed. This seems evident, also, when the total free fatty acid plus soap contents of the feces dried by the two methods are compared. The average total for the oven-dried material is 97 mg. per gram and for the cryochem-dried feces it is 96 mg. No real difference was found between the free fatty acid plus soap analyses made on samples prepared in the two ways, indicating that while the total remained unchanged there was a real change in its components. From these results it seems clear that when the fecal fat partition is to be determined, care must be exercised in selecting the method of desiccation if the analyses are to be performed on dried material.

*The experimental studies with normal children were made possible by the cooperation of the Methodist Children's Village, Detroit.

NITROGEN

One of the determinations most frequently performed on biological material is analysis for nitrogen, from the results of which the protein content may be calculated. During standing and dehydrating, the organic constituents are most susceptible to loss of nitrogen.[3] The effect of the cryochem procedure of desiccation on nitrogen content is illustrated by analyses of feces, urine, and milk.

Fecal Nitrogen.—The averages of results of determination of the nitrogen content of the feces of children who were subjects of a continuous metabolic balance study over a period of fifty-five days[14] are given in Table II. Each fecal sample represented a five-day period, and similar samples from each of several children were carefully collected and preserved, after preparing in the following manner: (1) A sulfuric acid digest[14] was made of one portion of the fresh feces and the nitrogen determined. This value has served as a standard for comparison. (2) A portion of the fresh feces was dried down, under alcohol, in a forced draught, steam heated oven below 70° C. (3) Another portion of the fresh feces was dehydrated by the cryochem process.

TABLE II

EFFECT OF DRYING METHOD ON NITROGEN CONTENTS OF FECES AND URINE

MATERIAL	METHOD OF PREPARING SAMPLE	NITROGEN*		CRITICAL RATIOS	
		MEAN ± SE_M	SD ± SE_{SD}		
Feces†	Acid digest	1380 ± 37	145 ± 26	Acid digest:cryochem dried	1.5
	Cryochem dried	1309 ± 31	120 ± 22	Acid digest:oven dried	5.3
	Oven dried	1125 ± 30	116 ± 21	Oven dried:cryochem dried	4.3

†From analyses of 15 samples.
‡From analyses of 88 samples.

From comparisons of the nitrogen contents of the preparations, drying in the oven caused a considerable loss of nitrogen, an average of 18 per cent of the nitrogen content of the acid digest of the fresh feces. The feces preserved by the cryochem procedure showed an average loss of only 5 per cent of the value determined for the acid digest, although the analyses were made two years after the samples had been dehydrated in the cryochem, and the loss was consistent for all samples. The children excreted in their feces, averages of 1,380, 1,309, and 1,125 mg. of nitrogen per day, as determined upon the acid digest, cryochem-dried, and oven-dried feces, respectively.

Statistical evaluation has been applied to the results obtained for the fecal nitrogen in 15 samples each of the acid digest, cryochem-dried, and oven-dried feces. The critical ratio (Table II) leaves some doubt as to the significance of the difference found between the nitrogen values for the acid digest and for the cryochem-dried samples, but the Analysis of Variance ($F = 51.68$; $F^1 = 8.86$) demonstrated a real difference. For the cryochem-prepared samples versus the oven-dried samples, the critical ratio (Table II) showed a real statistical difference, confirmed by the Analysis of Variance ($F = 89.67$; $F^1 = 8.86$). While the fresh samples contained slightly more nitrogen than the cryochem-

prepared samples, the latter had considerably greater nitrogen contents than the oven-dried samples. The real difference between the results obtained on the cryochem- and the oven-dried samples is evident from the values given in Table II and is confirmed by the critical ratio of 4.3.

Several explanations may be offered for the nitrogen loss shown by the cryochem-dried fecal material. Feces are known to contain approximately 40 per cent bacteria and volatile nitrogen compounds may already be present, or be formed even while the product is frozen. It is possible, also, that although the dried samples were stored in desiccators over desicchlora, they may have absorbed some moisture when the glass-stoppered bottles were opened to remove samples for other determinations. Despite the small loss of nitrogen from the feces dehydrated by the cryochem process and preserved for two years, it appears safe to conclude that this method of drying offers the best method for desiccating various biological materials with a minimum of chemical alteration.

Urinary Nitrogen.—A comparison has been made between the nitrogen contents of 88 samples of urine, as determined upon fresh and upon cryochem-dried samples. From the average data for these series of analyses the nitrogen contents of the two preparations appear similar (Table II). The averages were 9.52 and 9.60 mg. of nitrogen per milliliter of urine in the fresh and dried samples, respectively; the ranges of variation shown by the standard deviations (SD) correspond closely, and the critical ratio is only 0.5.

Milk Nitrogen.—Five samples of fresh milk were secured at weekly intervals and analyzed for nitrogen by the Kjeldahl method.[14] Portions of the same samples were dried by the cryochem procedure and the nitrogen similarly was determined. The averages for nitrogen, determined upon the dried and fresh samples, were 509 and 506 mg. per 100 Gm. of milk, respectively, which represents a difference of only 0.5 per cent in the nitrogen contents.

It should be pointed out in this connection that in determining the energy value of such substances as milk and urine in the bomb calorimeter, other methods of drying make it necessary to determine the nitrogen loss in drying and make a correction for this loss in calculating the heat of combustion of the original material. The cryochem desiccation process offers a means of eliminating the additional determination of nitrogen on the dried material and the nitrogen loss correction in the energy calculation.

SUMMARY

The removal of water from feces, urine, and milk by the cryochem process (dehydration *in vacuo* from the frozen state by means of chemicals) permits preservation of the dry material indefinitely in an undenatured form if stored under proper conditions. This method of dehydration has many advantages over oven-drying. Oven-drying at 70° C., and under, hydrolyzes the soaps in feces, causing exaggerated values for the free fatty acids and a reduction in the soaps, although the total free fatty acid plus soap values are the same for both methods of drying. The nitrogen contents of the cryochem samples of feces, urine, and milk approximate those of fresh specimens. In determining energy by the bomb calorimeter, the cryochem-dried material permits greater

accuracy in analyses and economy of time and materials, eliminating one nitrogen determination and correction for nitrogen loss in drying.

ON THE PURIFICATION OF GUM GHATTI*

L. F. Wicks, M.S., St. Louis, Mo.

ALTHOUGH the use of Nessler's reagent dates back to 1856, it was apparently Chiles[1] in 1928, who first emphasized the great gain in stability of nesslerized solutions when gum arabic was present. By its inclusion he successfully nesslerized Kjeldahl digests containing concentrations of ammonium ion far greater than is otherwise possible. Such application of a suitable protective colloid was indicated, of course, once the Nessler reaction color was suspected of being a colloidal suspensoid. Prussian blue sols, present in a micro glucose method, were stabilized with gum ghatti by Folin[2] in 1929. Looney[3] in 1930 employed this same gum for his simple blood urea method by direct nesslerization. A year later Walters[4] applied it to other nesslerized solutions, claiming gum ghatti to be much superior to Chiles' gum arabic, of which it is a variety.

As would be expected, the natural gums are very variable substances, and most samples contain interfering compounds, which can cause reduction of the double iodide of Nessler's reagent with the separation of what seems to be mercurous compounds. When Nessler's reagent is added to a water solution of most natural gums, a greenish-yellow turbidity appears, and slow precipitation follows. Fortunately, the colored ammonia complex of the Nessler reaction is less easily reduced but still turbidity often develops. These reducing materials are doubtless responsible for the limited use of the gums as an aid to nesslerization and for disagreement as to its value. For example, Looney found gum ghatti to retard greatly the rapid turbidity that follows in almost all direct nesslerization urea methods, while Hawk and Andes[5] reported increased turbidity.

Several investigators have tried to remove the objectionable reducing substances in the gum solution with only partial success. Oxidation was an evident approach. Chiles mentioned using sodium peroxide but discarded it and simply mixed a portion of Nessler's reagent with a greater volume of crude gum solution and waited for it to clear. Doneen[6] suggested Chiles' method of preparation whenever the gum solution proved too crude. Folin,[2] in preparing gum ghatti solution for the iron-reduction glucose method cited above, oxidized with potassium permanganate. Other analysts, such as Walters, and Lieboff and Koppel,[7] have precipitated the gum from aqueous solution by strong alcohol. Most workers, however, including Looney, and Daly,[8] used, if any, a crude solution. Herzfeld,[9] and Nichols and Willits[10] employed gelatin which has a much lower gold number[11] than the gums. We have tried tragacanthin, the soluble portion of gum tragacanth,[12] without much satisfaction.

*From the Research Department of the Barnard Free Skin and Cancer Hospital, St. Louis.

Received for publication, June 15, 1942.

EXPERIMENTAL

Although most samples of "soluble gum ghatti," or of gum arabic, include contaminations like woody fibers, earthy material, insoluble gum, and coloring matter, the impurities most objectionable from the view point of nesslerization are calcium, magnesium, and ammonium compounds, but especially the reducing substances.

The first problem is that of dissolving the gum. Some texts give directions for suspending the sample at the top of a cylinder of cold water where it requires days to disperse. Others lengthily stir the powdered gum with cold water, a method by which solutions up to 10 per cent are prepared, an unnecessary concentration, which is as viscous as syrup and cannot possibly be filtered or centrifuged. It is not only easier but better to prepare the solution hot, for it is thus somewhat less frothy and a little lower in reducing substances. Snell and Snell[13] recognized this, for while their directions call for a laborious dissolving of the gum in cold water, they then recommend heating the solution over a boiling brine bath "to destroy reducing enzymes."

We also attempted the destruction of the reducing substances by oxidizers, such as potassium mercuric iodide, triiodide, permanganate, hydrogen peroxide, etc., without much satisfaction. Permanganate, as used earlier by Folin, gives only partial improvement, and the deep brown oxide of manganese remains peptized in the gum solution.

The expedient of mixing some Nessler's reagent with a much greater volume of gum solution to clear out the reducing substances was found to have certain disadvantages. The alkali of the reagent seems at first to increase the reducing power of the gum solution, doubtless by hydrolysis and other reactions. Consequently, it is not practical to incorporate a small amount of protective gum solution with undiluted Nessler's reagent stock before use. Upon mixing the solutions, a very pronounced turbidity develops. After many days, the supernatant liquid is clear above a greenish or black residue of mercurous iodide or mercury. However, despite decomposition of the added Nessler's reagent and part of the gum, the final solution, though alkaline, is substantially lower in reducing substances. Unfortunately, use of such gum ghatti solution requires a special Nessler's reagent containing less alkali and more of the double iodide.

The alcohol precipitation technique is evidently based upon the assumption that the chief interfering substances are the salts associated with the gums. Addition of alcohol to an aqueous solution of a gum up to a concentration of 60 per cent or more[11] causes separation. Long contact of the precipitated gum with strong alcohol lowers its solubility in water. The sticky, demineralized mass is then dried, pulverized, and dissolved in water. This is a messy procedure and one which removes the salts but only a small portion of the reducing substances. One can prepare a better (but not good) gum ghatti solution by simply washing the powdered crude sample with hot alcohol, drying, dissolving in water to a 1 per cent solution, treating with permutit, and filtering.

True gums can also be precipitated from aqueous solution by basic lead acetate, but they are thereby denatured and are no longer water-soluble.

Turning then to the possibility of removing the interfering materials by adsorption, a variety of adsorbing agents was tried. Alumina gave fair results,

but this oxide is indicated[14] to attach pentosan gums. The clays, kaolin, and Lloyd's reagent were slightly effective, but they were so finely divided that it was almost impossible to separate the suspended particles. Silica in the form of kieselguhr had the same fault; ground silica gel did not, of course, but neither was it very active. The zeolite, permutit, besides removing calcium, magnesium, and ammonia, seemed to adsorb some coloring matter and reducing substances. However, adsorbtive carbons proved most satisfactory, especially purified bone charcoal, which we found can take out the greater portion of the reducing substances.

SUGGESTED PROCEDURE

Bring the desired volume of distilled water to a boil, and then transfer the beaker to a steam bath. Add enough of a good grade of powdered gum ghatti (e.g., Coleman and Bell "gum ghatti, soluble") to make a 1 per cent solution, and heat with frequent stirring for about one-half to three-quarters hour, or until all soluble material appears to be dissolved. (Heating over a direct flame can char the gum.) While still hot, filter with suction through a couple thickness of closely-woven cloth pressed down snugly in a Büchner funnel with a disk of wire screen. (Only the grosser particles will be retained, but even the coarsest crepe filter paper would soon clog.) Return the gum solution to the steam bath, add about 6 to 8 Gm. of dry, acid-purified bone charcoal powder per 100 c.c., cover with a watch glass, and heat with occasional stirring for one-half to one hour. Oddly, after the charcoal treatment, the viscosity of the gum solution is apparently greatly reduced, as it is then much more readily filtrable (although Rakuzin[14] states that gum arabic at least is not adsorbed by charcoal). Filter while hot through a fast crepe paper (e.g., Reeve Angel 202) in the Büchner funnel. The filtrate may be grayish, due to fine particles of carbon. If so, change the filter paper to a retentive one (e.g., Munktell OA) and refilter. For each 100 c.c. of the cool filtrate, add about 3 to 4 Gm. of *good* permutit (e.g., "according to Folin"—or purify as described by Hawk and Bergeim[15]). Agitate gently for around ten minutes and filter with crepe paper and suction.

"Bone charcoal" as often sold may consist of a great deal of calcium compounds (including sulfides) and a little partly decomposed organic matter along with the porous carbon. Use of such material can render the gum solution more impure than before. If acid-treated bone charcoal is not available, an ordinary grade (e.g., Mallinckrodt No. 4396) must be purified, as described by Hawk and Bergeim.[15] Over 80 per cent of the "charcoal" may dissolve in the hot, dilute hydrochloric acid. To avoid prolonged washing, the residue can be removed from the Büchner funnel after a couple hot water rinsings, suspended in a little sodium bicarbonate solution (test with litmus), then refiltered and washed again in the funnel. It is naturally important that the charcoal be free of any strong acid. The final product may be used over if washed well with hot water and dried in the oven. The permutit may also be washed, repurified, and used again.

ALTERNATIVE PROCEDURE

A method not quite as effective as the foregoing, but much more convenient, is as follows: Prepare the gum solution on the steam bath as outlined

but to only 0.5 per cent concentration. Filter hot through cloth as described previously, and add about 2 to 3 Gm. of a good alkali-free "activated" wood charcoal powder (e.g., "Activated Charcoal, Merck") per 100 c.c. Heat on the steam bath with frequent stirring for at least one-half hour. Filter hot with suction through crepe filter paper and then through a more retentive paper to catch the finer carbon particles. With wood charcoal these particles are smaller and lighter, and hence more difficult to remove. A lower concentration of the gum solution is necessary. The permutit treatment may often be omitted when wood charcoal is the adsorbing agent.

All the experiments outlined here were made by nesslerizing in the old Folin-Wu tubes in the presence of 1 c.c. of 1:1 sulfuric acid, and with the Koch-McMeekin reagent as prepared with mercuric oxide,[16] itself a rather stable reagent. As little as 5 c.c. of the purified 0.5 per cent gum ghatti will stabilize 1.5 mg. of nitrogen per 50 c.c. for hours, and 10 c.c. (or equivalent in 1 per cent) will serve for as high as 2.5 mg.

In adding the gum solution to the micro-Kjeldahl digest to be nesslerized, it is well to dilute that acid solution first to avoid any chance of possible hydrolysis of the pentosan gum.

Gum solutions will slightly lower the intensity of the Nessler color, doubtless due to the influence on particle size. They must naturally be added to the standard also.

As some molds grow readily in gum solutions, it is best to include a preservative. This must be one which causes no reduction when mixed with Nessler's reagent. Chloroform definitely gives marked reduction from contact with the alkali (formate?). Walters used water saturated with thymol, a good preservative but one which can cause a slight reduction. Toluol was found most satisfactory, only a few drops being required to prevent mold growth without refrigeration. (It is possible, by adding too much toluol and shaking very vigorously, to form a toluol emulsion.)

SUMMARY

Reducing substances naturally present in most samples of gum ghatti will often cause turbidity of Nessler's reagent when that protective colloid is employed. The greater part of the interfering materials can be removed by treatment of the hot gum solution with acid-washed bone charcoal (or less well by wood charcoal) followed by permutit. These procedures are described.

A NEW MODIFICATION OF THE THUNBERG METHOD FOR THE DETERMINATION OF DEHYDROGENASES IN TISSUES*

Ulrich Friedemann, M.D., and Alvin Hollander, M.S., Brooklyn, N. Y.

FOR the past two years we have carried out systematic studies on the effect of toxins and viruses on the dehydrogenase systems of tissues. The results of these investigations will be published in a separate paper. The classical method for this purpose, that described by Thunberg, requires special tubes which must be thoroughly evacuated and shaken during the entire course of the experiment. It was soon felt that this was too cumbersome for large-scale experiments. A modification was designed, therefore, which, without apparent disadvantages, permits the performance of many tests in a relatively short period of time. Instead of using evacuated tubes, the reagents were mixed with melted agar and the reaction was observed in the solidified medium. By this device anaerobic conditions were obtained, and, at the same time, sedimentation of the tissues was prevented.† Since we feel that this method may have other applications, we are presenting the technique in some detail.

Reagents.—

I. 2 per cent agar containing 0.5 per cent dibasic sodium phosphate and adjusted to pH 7.4.

II. 0.002 M methylene blue in distilled water.

III. Solutions of the various substrates. Succinate was used in 5 per cent solution and the others, citrate, glycerophosphate, glucose, and lactate, in equimolar concentrations. The pH of all solutions was adjusted to 7.1 with sodium hydroxide.

---

*From the Division of Bacteriology, the Jewish Hospital of Brooklyn.

Received for publication, June 15, 1942.

†After the elaboration of this method, Isaacs and Nussbaum[1] reported another modication of the Thunberg method for the determination of the dehydrogenases of bacteria. They suspended resting bacteria in saline and excluded oxygen by overlayering the fluid with vaseline. In our earlier experiments we used mineral oil for the same purpose but did not find it suitable for tissues. Because of the constant shaking required to prevent sedimentation of the tissue elements, the continuity of the oil layer was disrupted and oxygen gained access to the underlying fluid. The use of agar, therefore, is an essential feature of our technique.

IV. Tissue suspensions. The organs were finely ground with sand and 10 per cent suspensions were made in saline.

PROCEDURE

The agar was melted and 2.5 c.c. were put into each tube. When the agar had cooled to 42° C., 0.5 c.c. of methylene blue and 1 c.c. of substrate (both warmed to 37° C.) were added. This mixture was then added to 1.25 c.c. of tissue suspension, also previously warmed to 37° C. Complete admixture of the components were accomplished by rather vigorous rotation between the palms. Immediately afterwards the tubes were plunged into a freezing mixture of ice and salt in water and, when the agar had solidified, kept for an additional ten minutes in a refrigerator.

The tubes were then put into a water bath at 38° C. and observed for the decolorization of the methylene blue. If the tissues were ground finely enough, the time at which the end point of the reaction was reached could be determined accurately. Owing to some slight diffusion of oxygen from the air into the agar a narrow, well-demarcated zone of blue coloration was present at the surface but did not interfere with the reading of the results. In order to determine the degree of anaerobiasis in the agar, 1.25 c.c. of tissue suspension and 1 c.c. of a 1 per cent solution of paraphenylenediamine hydrochloride (neutral to litmus) were added to 2.5 c.c. of agar and handled as described above. A hazy gray color appeared in the agar indicating the presence of a trace of oxygen. This color, however, disappeared within a few seconds except for a well-defined, narrow black band at the surface. We may conclude from this observation that within a few seconds after the start of the experiment, the agar is free from oxygen. The quantitative relationship between the time required for decolorization and the amount of dehydrogenase will be discussed in a subsequent paper.

In order to test the reproducibility and consistency of the results, tests were done with the organs of two animals using succinate as a substrate. In both series each individual organ was tested five times under exactly the same experimental conditions. From the experimental data the arithmetic means and the standard deviations were calculated and are recorded in Table I.

TABLE I

DETERMINATION OF SUCCINASE ACTIVITY IN VARIOUS SAMPLES OF THE SAME ORGAN

ORGAN	EXPERIMENT I		EXPERIMENT II	
	MEAN*	STANDARD DEVIATION*	MEAN*	STANDARD DEVIATION*
Kidney	19.8	± 0.68	9.1	± 0.26
Liver	18.8	± 0.68	10.4	± 0.20
Heart	16.0	± 0	10.9	± 0.90
Brain	28.4	± 3.4	30.2	± 1.99

*Time in minutes.

The values of the standard deviations show that the results in each experiment with kidney, liver, and heart are consistent. In the experiments with brain, the results vary more considerably, although the experimental conditions were kept strictly constant. This probably is due to the well-known chemical instability of brain suspensions.

It may be seen from these two experiments that there are large differences in the dehydrogenase contents of the organs of various animals. Table II shows the results of experiments with the organs of 20 animals. Again we confine ourselves to determinations of succinase.

TABLE II

DETERMINATION OF SUCCINASE ACTIVITY IN THE ORGANS OF 20 ANIMALS

ORGAN	MEAN*	STANDARD DEVIATION*
Kidney	19.2	± 4.13
Liver	21.7	± 5.53
Heart	24.9	± 6.08
Brain	46.8	± 15.47
Adrenals	36.8	± 8.72

*Time in minutes.

These results show that any comparison between normal and pathologic organs can be made only on a statistical basis.

SUMMARY

A new modification of the Thunberg method for the determination of dehydrogenases in tissues has been reported. Tissue suspensions, methylene blue, and substrates are mixed with melted agar and decolorization observed in the solidified medium. The agar provides anaerobic conditions and prevents sedimentation of the tissue elements. The simplicity of this method permits the carrying out of large-scale experiments in a short period of time.

A PHOTOELECTRIC METHOD FOR THE DETERMINATION OF POTASSIUM IN BLOOD SERUM*

JOSEPH M. LOONEY, M.D., AND CORA G. DYER, M.S., M.T., WORCESTER, MASS.

THE growing importance of potassium in physiologic investigations is attested to by the multiplicity of methods proposed for its determination. This fact is also evidence that none of the methods so far used has received general acceptance as wholly satisfactory and reliable. In our studies on the metabolism of schizophrenic patients we have used many methods, but most of our results have been obtained by the silver cobaltinitrite method of Breh and Gaebler,[1] modified by the procedure of Taylor,[2] for handling the standard. We have not been entirely satisfied with this method as the degree of error was too high to allow the detection of small but significant changes. When the extinction coefficient for the color developed by this method on known potassium solutions was determined on different days, there was a marked divergence of values, especially at the higher levels. The results for different concentra-

*From the Memorial Foundation for Neuro-Endocrine Research and the Research Service of the Worcester State Hospital, Worcester.

Received for publication, June 22, 1942.

tions of potassium obtained at the same time followed Beer's law but were not consistent from day to day. Truzkowski and Zwemer[3] subjected the method to a critical analysis and recommended that the precipitation be carried out between 17° and 22° C. Robinson and Putnam,[4] however, claimed that greater sensitivity can be obtained by precipitating from a 30 volume per cent alcohol medium at 4° to 6° C.

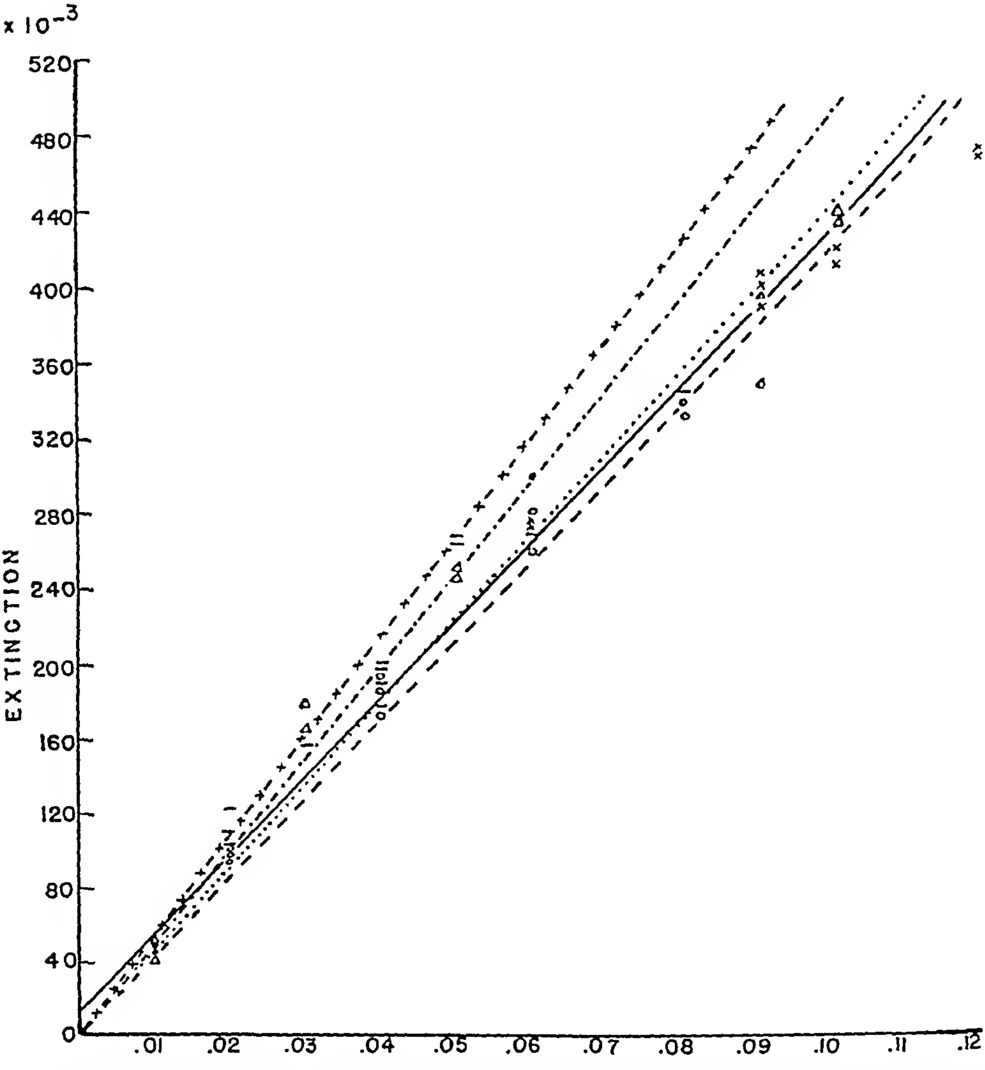

Fig. 1.—Variations in extinction produced by same amounts of potassium on different days with sulfanilic acid and α-naphthylamine. Temperature of precipitate held 20° to 23°. 1 c.c. of $AgNO_3$ = 20 c.c. of cobaltinitrite.

Harris[5] used a modification of the Breh and Gaebler method by precipitation from a 14 per cent alcoholic solution in a water bath at 20° C. for one-half hour. This period is much shorter than that recommended by most authors, and we have found it insufficient to obtain complete precipitation in very dilute solutions. Harris stated that the temperature could vary from 16° to 25° C. without change in the potassium/nitrite ratio. Our results indicate that the optimum range is between 18° and 20° C., since the potassium/nitrite ratio is

not constant above 23° C. and there is a tendency for fine needles of silver nitrite to precipitate below 16°. We have adopted his procedure of washing with an alcohol-ether-water mixture, since it is definitely superior in preventing flotation of the fine precipitate.

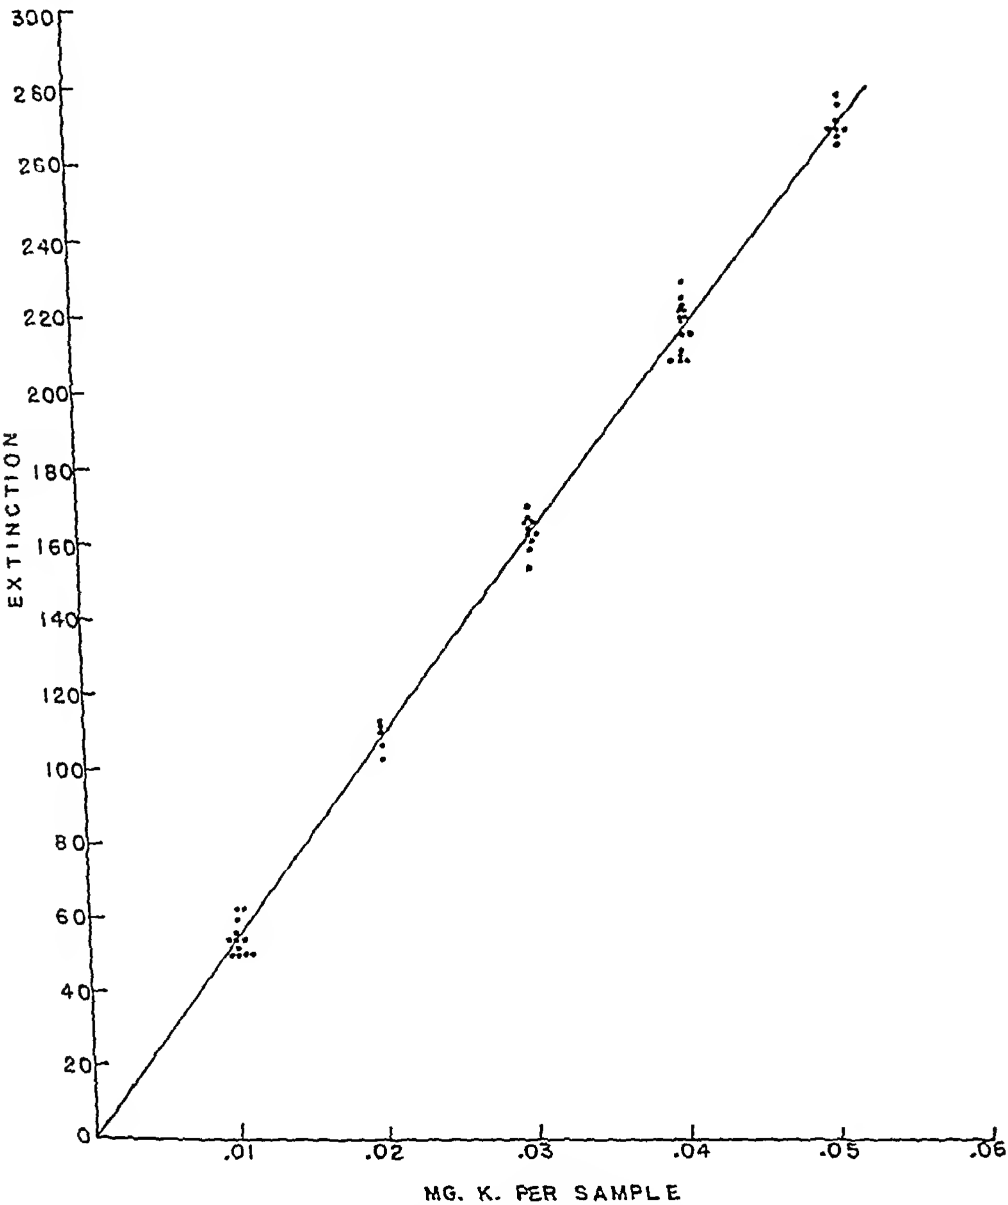

Fig. 2.—Extinction values for potassium silver cobaltinitrite with sulfanilamide and N-1 naphthylethylenediamine dihydrochloride.

The preparation of protein-free precipitates was also investigated. The commonly used Folin-Wu tungstic acid procedure plus silver nitrate was frequently followed by slightly cloudy filtrates which gave inconsistent results. The use of zinc sulfate and sodium hydroxide in combination with silver nitrate gave clear filtrates, but the results on known solutions were usually too high.

The use of sulfosalicylic acid plus silver nitrate was ruled out, because the results were high due to a reaction between the acid and the coupling agents used for the subsequent colorimetric procedure. Trichloroacetic acid could not be used, since all the samples that we tried gave turbid solutions with silver nitrate.

Weichselbaum, Somogyi, and Rusk[6] recommended the use of copper sulfate to replace the sulfuric acid in the preparation of filtrates. Our experience indicates that this method gives satisfactory results. They also recommended changes in the preparation of the silver cobaltinitrite reagent, but we were not able to obtain the results that they claimed for this modification and, therefore, returned to the use of the reagent of Breh and Gaebler.[1]

The chief difficulty in the use of a photoelectric colorimeter and a *standard* absorption curve arises from the variability in the amount of color produced by identical amounts of potassium on different days. This variability, as is shown in Fig. 1, arises from changes which occur in the solutions of sulfanilic acid and α-naphthylamine. Another disadvantage of these reagents is that the color produced is not stable and begins to fade after it attains its maximum development in about five to ten minutes.

It was felt that the substitution of the coupling reagent of Marshall[7] N-1 naphthylethylenediamine dihydrochloride for α-naphthylamine and sulfanilamide for sulfanilic acid might be advantageous. Shinn[8] has found these substitutions to give superior results in the determination of nitrite in foods, water, and sewage. We have been able to confirm her findings with regard to the permanence of the color produced by the Marshall reagents. Whereas the sulfanilic acid and α-naphthylamine showed a fading from an absorption reading of 77.2 per cent to 70.8 per cent on standing for twelve hours, the same amount of nitrite with the Marshall reagents showed a decrease in color only from 82.5 per cent to 81.8 per cent. The intensity of color was also considerably greater with the latter reagents. Although Shinn stated that the reagents would give satisfactory results for one month, we have found that values cannot be relied upon after a week when using the standard curve, and so we prepare these solutions fresh each week. If two standard solutions are run through at the same time as the unknown solutions, then satisfactory values can be computed from the line drawn through these two points for solutions kept up to a month. It should be noted, however, that the line must pass through the origin, and if this does not occur, some error has been made and new standards must be run.

TABLE I

Mg. of K per 100 ml. final volume	0.002	0.004	0.006	0.008	0.010	0.012	0.016	0.018	0.020	0.024

PROCEDURE

All glassware must be kept scrupulously clean. We have found it convenient to keep a set of glassware for use in potassium determinations only. The presence of ammonia will give falsely high results. Therefore, ammonia fumes must be avoided and tubes, must be capped at all times when not in manipulation. The silver concentration is also important, since an excess of

silver as well as low temperatures during the cobaltinitrite precipitation will give long needlelike crystals of silver nitrite which interfere with the results. For this reason, we have reduced the silver content of Breh and Gaebler's reagent by one-half.

A. *Precipitation of Protein and Chloride.*

1. To a clean test tube, add
   0.5 c.c. of serum,
   7.0 c.c. of distilled water,
   1.0 c.c. of 1.5% sodium tungstate, and mix
   1.0 c.c. of 2.5% copper sulfate.
   Stopper and shake well. Then add
   0.5 c.c. of 2.5% silver nitrate.
   Restopper and shake again.
2. Let stand for fifteen to twenty minutes and filter through a Whatman No. 5 paper. The first portion of the filtrate should be refiltered through the same paper in order to be sure of an absolutely clear solution, since a cloudy filtrate apparently gives a low result.

B. *Precipitation of Potassium With Silver Cobaltinitrite.*

1. To a clean 15 c.c. graduated centrifuge tube, add
   3 c.c. of the protein chloride-free filtrate,
   1 c.c. of 95% alcohol, and
   1 c.c. of distilled water.
2. Place in a water bath at 18° to 22° C. for five minutes.
3. Add 2 c.c. of silver cobaltinitrite reagent, cap and mix (by tapping, not by inversion), and replace in the water bath for two hours.
4. Centrifuge for fifteen minutes at 2,800 r.p.m.

C. *Washing the Precipitate.*

1. With a capillary pipette remove the supernatant fluid to the 0.2 c.c. mark.
2. Wash with 7 c.c. of wash reagent, rinsing down the sides and disturbing the precipitate as little as possible. If the tube is slanted, the remaining 0.2 c.c. of fluid will mix with the wash solution.
3. Centrifuge for fifteen minutes, decant, invert, and drain over filter paper for five minutes. Wipe the mouth of the tube.
4. Repeat this washing and draining twice more.

(After this stage, and only at this point, the procedure may be interrupted and the tubes allowed to stand overnight if one drop of distilled water is added to each tube to prevent the precipitate from drying up.)

D. *Digestion.*

1. Add 10 c.c. of approximately 0.2 N sodium hydroxide, breaking up the precipitate if possible.
2. Heat in a boiling water bath for ten minutes. A black precipitate remains.
3. Cool, make up to 10 c.c. with water, stopper, and mix. Replace stopper with centrifuge cap and centrifuge for five to ten minutes.

E. *Colorimetry.*

1. To a 100 c.c. volumetric flask, add
   2 c.c. of supernatant fluid from D,
   5 c.c. of distilled water,
   1 c.c. of 50% hydrochloric acid, and
   2 c.c. of 0.5% sulfanilamide.
2. Mix and let stand for three minutes, then add 1 c.c. of 0.1% N-1 naphthylethylenediamine dihydrochloride.
3. Make to volume and read after five minutes.

F. *Reagents.*

1. 1.5% sodium tungstate.
2. 2.5% copper sulfate.
3. 2.5% silver nitrate.
4. 0.2 N (approx.) sodium hydroxide.
5. 40% silver nitrate.
6. Sodium Cobaltinitrite Solution.[5]
   A. Dissolve 25 Gm. of cobalt nitrate crystals in 50 c.c. of water and add 12.5 c.c. of glacial acetic acid.
   B. Dissolve 120 Gm. of sodium nitrite in 180 c.c. of water (must be potassium free). Add 210 c.c. of B to all of A, and aerate the solution under the hood until all the nitrous oxide fumes are driven off. Place in the refrigerator where it will keep for about a month. *Filter each time before using.*
7. Cobaltinitrite Reagent.
   To 20 c.c. of filtered sodium cobaltinitrite solution, add 1 c.c. of 40% silver nitrate.
   Shake well and filter to remove trace of precipitate which is undissolved.
8. Sulfanilamide Reagent.
   0.5% sulfanilamide in 30% acetic acid. Must be prepared fresh weekly.

9. Coupler Reagent.
   0.1% N-1 naphthylethylenediamine dihydrochloride in 30% acetic acid. Must be prepared fresh weekly.
10. Wash Reagent.
   2 volumes alcohol.
   1 volume ether.
   2 volumes water.

A standard curve was established by carrying out the foregoing procedure on standard potassium sulfate solutions containing 0.01 to 0.12 mg. of potassium per sample. The extended readings were obtained with a Lange photoelectric colorimeter against a water blank using a green filter having maximum transmission at 5,200 A.U. The results for values up to 0.05 mg. per sample are plotted in Fig. 2. As only one-fifth of the digested cobaltinitrite is taken for the final colorimetric reading, the absolute value of the potassium determined ranges from 0.002 to 0.010 mg.

It will be noted that the line which passes through the mean value for each concentration passes through the origin and follows Beer's law without deviation. Above 0.05 mg. of potassium per original sample the curve falls off sharply. This may be seen in Table I where the extinction constant K was calculated according to the formula $K = \frac{E}{CT}$, where E equals the extinction, C = the concentration of potassium in milligrams per 100 c.c. of final volume, and T = the thickness of the solution through which the light must pass, which, in our tubes, is 1.2 cm.

In the usual procedure the concentration of the potassium in the final solution of the standard is 0.012 mg. and the readings are made at a point at which the color does not follow Beer's law.

Our method, therefore, has been adjusted to give readings corresponding to 0.006 mg. of potassium in the final solution. This is in the region in which there is no deviation from Beer's law and allows determinations to be made on serums containing up to 35 mg. of potassium per 100 ml. without dilution. This would cover the entire range which might be encountered in ordinary clinical practice.

Having established our table of values for known potassium, a series of blood serums were run to which varying amounts of potassium were added. The recovery values may be seen in Table II. It is interesting to note that, although different serums were used in each experiment, there is no wide variation in the potassium value for the serum alone. Cases 8 and 12 had an undetermined amount of potassium added before the known amount was added, which accounts for the high initial values in these two cases.

It will be noted that the determinations made in multiplicate on the original serum show a mean difference from the average value of each serum of only 0.15 mg., and this value is elevated somewhat by the poor result obtained in Case 5 where a difference of 1.78 mg. between the highest and lowest readings was found. If we exclude this case, the maximum difference between the highest and lowest readings of any serum was 0.56 mg. The mean error in the recovery of the added potassium was 1.89 per cent.

SUMMARY

A modification of the silver cobaltinitrite method for the determination of serum potassium adapted for use with a photoelectric colorimeter is described. By the use of sulfanilamide and N-1 naphthylethylenediamine dihydrochloride to determine the concentration of nitrite in the potassium silver cobaltinitrite precipitate a stable color is produced which is sensitive to 0.002 mg. of potassium in 100 ml. of solution. The color produced follows Beer's law up to a concentration of 0.01 mg. of potassium in the final solution, which would correspond to a serum potassium value of 33.3 mg. per 100 ml.

THE MICRODETERMINATION OF CHLORIDES IN VISCOUS BIOLOGICAL FLUIDS AND ITS RELIABILITY*

FRANKLIN HOLLANDER, PH.D., AND JULIUS STEIN, B.S.
NEW YORK, N. Y.

THE need for a simple, rapid, and reliable method for determining micro quantities of chloride in 0.1 ml. samples of biological fluids like blood and viscous mucus is widely recognized, but no procedure which satisfies all these requirements is as yet available. Some adaptation of the Volhard titration (e.g., the method of Van Slyke[16]) would seem to be eminently suitable for the purpose, were it not that the precision of the silver thiocyanate titration is so poor as to rule this technique out of consideration for quantities of chlorine as low as 100 γ. In spite of the popularity of the Wilson and Ball[19] modification of the Van Slyke method for quantities around 3 to 5 mg., occasional articles which call attention to its poor reliability are still being published (e.g., Schales and Schales[12]). The chief cause of this inadequacy is the transience of the end point, which results from the dissociation of the ferric thiocyanate into its colorless constituents, aided

*From the Laboratories of the Mount Sinai Hospital, New York City.
This work was supported in part by a grant from the Friedsam Foundation.
Received for publication, June 25, 1942.

by the conversion of precipitated silver chloride to silver thiocyanate in consequence of the greater insolubility of the latter. Rosanoff and Hill[16] reported that this difficulty in the Volhard titration can be overcome in part by filtering off the silver chloride before titrating the excess silver with thiocyanate, but scrutiny of their data leaves some doubt regarding the relative magnitudes of the errors with and without such filtration. In order to save the time and labor of filtration, Keys[5] adopted the technique of Fiske and Sokhey,[2] and centrifuged before titrating in order to remove the silver chloride precipitate by packing it at the bottom of the titration tube. However, Kolthoff[7] has pointed out that separation of the silver chloride entails the removal of silver-ion by adsorption, and Whitehorn[17] found no improvement whatever as a result of such filtration. These reports led to the use of various chemical agents for reducing the transience of the end point. Smirk[14] reported that acetone in conjunction with alcoholic thiocyanate sharpens the end point by decreasing the dissociation of the ferric thiocyanate, but this effect was not confirmed by Wilson and Ball.[19] The use of nitrobenzene for the same purpose was advocated by Caldwell and Moyer[1]; and Keys[6] employed ether to collect the silver precipitate at the liquid-liquid interface and thus to reduce back reactions in the water phase, according to the principle of Rothmund and Burgstaller.[11] Toluene and benzene have been recommended by Stschigol[15] for the same purpose, but none of these techniques has as yet been generally adopted.

The method of Wilson and Ball has been in use in this laboratory for many years, but we also have never been satisfied with its reliability. Multiple titrations on the same solution are often in very poor agreement, particularly when they are done on different days. The magnitude of these errors is well illustrated by the two series of data for a set of 24 single determinations on the same solution, performed over a period of eight weeks (experiment G 33-9). For the titration of the blanks (2 ml. of 0.2 N silver nitrate, titrated with about 0.5 N potassium thiocyanate) the standard deviation of the entire distribution (s) was 0.0017 meq.* and the mean (M) was 0.394 meq. For the corresponding "unknown" titrations (2 ml. of 0.2 N silver nitrate + 0.5 ml. of 0.1 N sodium chloride) $s = 0.0015$ meq. and $M = 0.344$ meq. Hence, for the 24 titers of the sodium chloride, alone, calculated by difference of blank and unknown, $M = 0.050$ meq. and $s = \sqrt{(0.0017)^2 + (0.0015)^2} = 0.0023$ meq., or 4.6 per cent of the mean (see Addenda, especially equations 4 and 7). Two other sets of similar data (G 33-7 and 8) were in statistically reasonable agreement with these values, and they are all well within the experience of other laboratories in the use of such modifications of the Volhard method. These results, therefore, afford a fair measure of the poor precision of this method as ordinarily carried out. Since these titers were not correlated with the date of titration, there is no reason for suspecting a progressive change in concentration of any of the reagents on standing, and this is supported by the identity of the mean titers for sodium chloride in all three sets of data. Attempts to correlate the error with color intensity of the end point or with individual operator have been unsuccessful.

*All titers and standard deviations deri[illegible] reported in milliequivalents instead of milliliters of potassium thiocyan[illegible] acilitate the comparison of observations on different unknowns, and of [illegible] of different concentrations or volumes.

The afore-mentioned titrations were all performed in the presence of nitrobenzene, since without this substance (or with ether or acetone) the end point is even less reliable than with it. According to Caldwell and Moyer, the efficacy of nitrobenzene depends on its formation of "an insoluble layer over the precipitate, so that the rate of solution of the silver chloride is reduced to such an extent that it does not interfere in the thiocyanate titration," but a perfectly clear supernatant fluid is not essential. In our experience the silver precipitate appears to be removed by suspension within the layer of nitrobenzene, and this process rarely occurs completely. The action of the nitrobenzene can be reversed by the addition of more silver nitrate after the end point has been reached, and this explains why the removal of precipitate occurs only as one approaches the end point where the silver ion concentration is low. In our efforts to reduce the variability of our results we noticed that the uniformity of the titers increased with the completeness of removal of the precipitated silver salts by the nitrobenzene. Furthermore, the completeness of separation of the precipitate from the aqueous layer seemed to increase with the duration and vigor of shaking after each addition of reagent. Caldwell and Moyer state that agitation for thirty to forty seconds is necessary in order to form large spongy flakes, but they apparently did not associate such formation with the retention of these flakes within the nitrobenzene layer. Accordingly, we performed four series of titrations (G 33-10, 11, 12, and 13) by essentially the same procedure as before, except that additional precautions were taken in respect to the vigor and duration of shaking. The results showed marked and consistent improvement over those obtained without this innovation in technique. Thus, a pooled estimate of s (see Addenda, equations 8, 9, and 10) from all 6 sets of data *without systematic agitation* ($N = 170$) is 0.0016 meq., whereas for the 8 such sets on blanks and sodium chloride solutions *with active shaking* ($N = 290$), s is 0.0004 meq. This indicates a fourfold improvement in the precision—a result which was confirmed by similar titrations on standard hydrochloric acid solutions and oxalated whole blood (G 33-10, 12, and 13).

Our experience with the shaking technique has been so consistently good that there can be no doubt regarding the reason for the improvement in reproducibility of titration; i.e., *the systematic removal of silver precipitate from suspension in the aqueous phase by means of vigorous shaking with nitrobenzene.* Nitrobenzene has not always been efficient in yielding good agreement among multiple titrations, but this has resulted merely from the lack of adequate shaking of the titration mixture. The influence of stirring upon the rate of fading of the end point and, therefore, upon the titer, in the absence of nitrobenzene, was pointed out by Short and Gellis,[13] but Whitehorn[19] subsequently reported identical results with mild and with vigorous stirring. In consequence, the importance of intensive agitation in the Volhard titration has been generally neglected (Keys[5] does stir the titration mixture, by means of a jet of air, but only to insure uniformity of titration rate). However, our own observations leave no doubt of its importance for optimum reproducibility of the end point, particularly in view of the large number of titrations used for the estimation of the precision measures.

We have, therefore, adapted this technique to the determination of minute quantities of chlorine (as low as 90γ), and our results have been entirely consistent with expectations based on our experiences with the larger quantities. In order that the procedure may be applied to biological liquids of high viscosity (like mucous secretions) without loss of precision, we have modified the usual pipetting technique—but this may be disregarded for fluids of low viscosity.

PROCEDURE

Reagents.—Silver nitrate (about 0.2 normal, not standardized), sodium chloride (0.1 normal, standardized gravimetrically, $s_M = 0.0004$ N), potassium thiocyanate (about 0.01 normal, not standardized*), ferric alum (6 per cent), nitrobenzene, and concentrated nitric acid.

The procedure is as follows:

1. Pipette 0.1 ml. of silver nitrate into each of a series of pyrex test tubes, 200 mm. by 24 mm. (outside diameter); designate 2 of these as "blanks."

2. Into each of 2 other tubes containing silver nitrate pipette 0.1 ml. of sodium chloride solution; these tubes are designated "NaCl standards" and serve in effect for the standardization of the potassium thiocyanate reagent.

3. Into each of another set of 2 or 3 tubes containing silver nitrate, introduce 0.1 ml. of the unknown solution, using the same pipette† for unknowns as for sodium chloride standards. With viscous liquids rinse the pipette twice with nitric acid and once with water—in which case the sodium chloride standard must also be delivered with rinsing.

4. To each tube add 1 ml. of nitric acid, less whatever may have been employed for rinsing. Cover the tube with a small watch glass and digest the contents on a water bath until the liquid becomes clear; this usually requires from one to two hours. Blanks and controls need not be digested, since their titers are the same with and without heating. Solutions brought to this stage can be stored in the dark for several days, or in dim diffuse light for one day, without any appreciable difference in titer.

5. After removing the tubes from the steam bath, cool and add 0.5 ml. of ferric alum and 6 drops (about 0.2 ml.) of nitrobenzene to each.

6. Titrate with the thiocyanate solution, using a 10 ml. burette graduated in 0.02 ml. A burette tip consisting of a hypodermic needle fitted to a Luer adaptor and the adjustable drop control device previously described (Hollander[3]) permit the addition of small volumes of reagent (0.003 ml.) with a minimum of time and effort. Add the thiocyanate slowly with frequent vigorous shaking, until the precipitate conglomerates into large flakes and is taken up by the nitrobenzene at the bottom of the tube. Slight opalescence in the supernatant fluid, caused by droplets of nitrobenzene, does not interfere with the end point nor reduce the precision of the method. As the end point is approached, shake the titration mixture vigorously after the addition of each drop of thiocyanate, for it is of the utmost importance that the precipitate be taken up entirely by the nitrobenzene at this stage. The nitrobenzene layer is broken up by this

*This solution is prepared with merthiolate (1:25,000) and then filtered to prevent the growth of organisms.

†These pipettes need not be calibrated, for reasons which are given later in this section. To facilitate their manipulation, without sucking the viscous specimen up above the graduation mark, we employ a special mechanical manipulator described elsewhere (Hollander and Stein[4]).

procedure, but it re-forms each time into an opaque spheroidal mass. The end point is indicated by the first faint orange-red tint of the supernatant liquid; under these conditions it is invariably stable for ten minutes and usually for much longer.

7. The concentration of chloride in the unknown, $[Cl]_{unk}$, is calculated by means of equation (2), in which the symbols have the following meanings: v = volume in milliliters of thiocyanate reagent required for unknown, blank, or sodium chloride standard as indicated by the subscript; ml = volume in milliliters of sample pipetted out; $[Cl]_{NaCl}$ = chlorine concentration of the standard sodium chloride solution.

$$[Cl]_{unk} = [Cl]_{NaCl}\left(\frac{v_{blank} - v_{unk}}{v_{blank} - v_{NaCl}}\right)\left(\frac{ml_{NaCl}}{ml_{unk}}\right) \qquad (1)$$

Since the same pipette is used for unknown and for standard solutions, the last factor on the right becomes unity. Then, representing $(v_{blank} - v_{unk})$ by Δv_{unk} and $(v_{blank} - v_{NaCl})$ by Δv_{NaCl}, we have

$$[Cl]_{unk} = \Delta v_{unk}\,\frac{[Cl]_{NaCl}}{\Delta v_{NaCl}} \qquad (2)$$

The expression $[Cl]_{NaCl}/\Delta v_{NaCl}$ is a constant factor for any set of reagents, and this greatly simplifies the calculations required for a long series of analyses.

Van Slyke applied a negative "empirical" correction to each titration reading, because an excess of 0.04 ml. of reagent was necessary to give a decided end point. Keys stated that any method which omits separation of the precipitate from the titrated fluid yields titers which are slightly too high; this error might also be obviated by a correction term similar to Van Slyke's. The titers which we obtained without the effective transfer of the silver precipitate to the nitrobenzene layer were significantly higher than the values obtained by means of vigorous shaking, and this is qualitatively in agreement with the observations of Keys. However, our method of calculation obviates the use of any such correction term, because it would occur twice in the calculation of each Δ v-value and, therefore, cancel out completely.

It will be noted also that the foregoing procedure obviates the independent macrostandardization of the potassium thiocyanate solution, since the same end is attained by titration of the sodium chloride standard. The constancy of concentration of the reagent over a period of several months is demonstrated by the small scatter (s) of the data for blanks and sodium chloride standards throughout any one series of titrations, and, therefore, the titrations of blank and sodium chloride standards need be done infrequently. In view of the trouble commonly encountered with deterioration of thiocyanate solutions, this constancy of its concentration is particularly noteworthy, and we ascribe it to the preparation of the reagent with merthiolate and filtration.

RELIABILITY OF THE METHOD

The reliability of an analytical procedure may be evaluated from the point of view of its accuracy (i.e., agreement between estimated and actual values; correctness) or of its precision (i.e., agreement among different estimates of the same value; reproducibility). In the following discussion the reliability has been considered from both of these angles.

As a measure of the *precision* of the method we performed a set of determinations on each of several solutions: standard hydrochloric acid in different concentrations, gastric mucous secretion, stomach contents, and oxalated whole blood. The number of titrations comprising each series and the statistical data are presented in Table I. In all but one of these series, the individual titrations were performed at various times throughout an interval of five weeks or more. The quantities of chlorine contained in the 0.1 ml. samples of the unknowns varied from 91 γ to 439 γ, corresponding to concentrations of 26 to 124 mN.

Now, in calculating the chlorine concentration of any solution, we actually employ three different titers: for blank, for sodium chloride standard, and for the unknown itself. For the first two of these, we ordinarily use mean values obtained from a large number of titrations (e.g., series 3a and 3b); for the unknown, however, we usually employ a mean of two, or at most three, titrations. Referring to equation (1), we see that s_M for $[Cl]_{unk}$ must be a function of the standard error of all three of these averages—v_{blank}, v_{NaCl}, and v_{unk}. But, since N for the two former is large compared with N for the unknown the s_M values for the former are negligible with respect to s_M for v_{unk} (see equation 5). Consequently, s_M for a Cl determination in triplicate may be taken equal to s_M for the titer of the unknown alone, and this is equal to $s/\sqrt{3}$, where s is the standard deviation of the titration itself. From the data in the table it appears that s varies from 0.00009 to 0.00016 meq., and that these values are not correlated with the mean titer. Hence, the most representative estimate of s for a titration is given by a pooled estimate* made from all 8 series, with a total of 81 individual titrations (N); by equation (11) this possesses the value 0.00010 meq. Therefore, $s_M = s/\sqrt{3} = 0.00006$ meq., and this is the precision measure for a titration done by this method in triplicate.

It must be remembered that the standard deviation observed for any other set of determinations may differ from this population estimate by amounts within the usual limits of statistical variation. Because of the very small number of titrations employed for any one determination, these differences may be relatively large. Furthermore, a percentage evaluation of precision (by means of the coefficient of variation, V) will vary with the magnitude of M according to equation (6). Thus, for a determination on 100 γ of chlorine (0.0028 meq.), V = 2.1 per cent, whereas for 0.5 mg. V is one-fifth of this, or 0.4 per cent. In general, therefore, the standard error in milliequivalents affords a more significant precision measure for an analytical method than does the coefficient of variation.

High viscosity of the unknown specimen does not affect the reliability of the method. This is shown by comparing s for determinations on mucus, blood, and stomach contents (series 6, 5, and 14) with the values for inorganic solutions (series 3a-3c). The good agreement among these statistics results in great measure from our practice of delivering the sample for analysis by rinsing the pipette and our precaution not to draw the sample up above the graduation in the first place.

*The chi-square test for homogeneity of the variances (s^2) justifies the taking of such a pooled estimate.

An estimate of the *accuracy* of this method can be obtained by comparing its results with those determined by a macromethod on the same solution. For this purpose, three solutions of hydrochloric acid were prepared from a carefully standardized stock solution, the concentration of which was 100 normal by titration with sodium hydroxide (which in turn had been standardized against potassium acid phthalate). A gravimetric determination of chlorine in this solution as silver chloride gave a value of 99.9 mN. Based on the mean of these

TABLE I

SUMMARY OF MICROCHLORIDE TITRATION DATA

SERIES	SOLUTIONS TITRATED WITH KCNS (0.01 N)	NUMBER OF TITRATIONS	MEAN TITER* N	±S✦ (MEQ.)	ESTIMATED Cl CONCENTRATION	AMOUNT OF Cl

----	0.1 ml. oxalated whole blood by difference		0.0075		75.1	266

*Mean amount of potassium thiocyanate used in each titration (in milliequivalents).

†The mucus specimen was collected from a Pavlov pouch in the absence of acid secretion. The sample was extremely viscous and was homogenized before pipetting.

‡This specimen was a sample of fasting contents taken from a dog by means of a Rehfuss tube.

✦s The standard deviation of a single titration.

two values, the three solutions contained the following concentrations and quantities of chlorine: 100.0 mN (354 γ), 50.0 mN (177 γ), and 25.0 mN (89 γ). Six microdeterminations were performed on each of these solutions. The results are summarized in Table I (series 3c, d, and e), and the estimated concentrations are 99.8 mN, 50.4 mN, and 25.8 mN, respectively. These data afford ample evidence of the accuracy of this method.

SUMMARY

1. A considerable improvement in the Van Slyke method for the determination of chlorides in biological fluids can be effected by the addition of nitrobenzene to the titration mixture, as recommended by Caldwell and Moyer, provided the liquid be agitated in such a way as to keep the precipitated silver salts adsorbed to the nitrobenzene layer. The procedure so modified is described in detail.

2. The accuracy and the precision of the method are determined in the range of approximately 100 to 500 micrograms of chlorine (0.1 ml. specimens with a concentration range of 25 to 125 mN). The standard deviation of a single titration, based on a pooled estimate from 81 titrations, is 0.00010 meq., or 1 mN. For a determination done, say, in triplicate, the standard error is 0.00006 meq., or 0.6 mN.

3. This high precision applies to liquids of high viscosity like mucus secretion as well as to hydrochloric acid solutions, provided the samples taken for analysis are pipetted with the proper precautions.

ADDENDA

1. Let

A_i = any one of a series of titers,
N = the number of titers in the series,
M = the mean of this series.

Then, the standard deviation for the series (and hence for a single titration) is given by s in the following equation:

$$s^2 \text{ (or } s_A^2) = \frac{\Sigma(M - A_i)^2}{N} \qquad (3)$$

For the performance of various "tests of significance," it is customary to adjust s^2 with the factor $N/(N-1)$, particularly when $N \leqslant 25$, in order to obtain an estimate of the population variance from that for a sample. This yields:

$$s^2 = \frac{\Sigma(M - A_i)^2}{(N - 1)} \qquad (4)$$

In the present work we are concerned only with a description of errors and not with tests of significance, but we have made this adjustment as a matter of routine. Then the standard deviation of the mean (i.e., the standard error) is given by s_M:

$$s_M^2 = \frac{s^2}{N} = \frac{\Sigma(M - A_i)^2}{N(N - 1)} \qquad (5)$$

and the corresponding percentage value, the coefficient of variation, is given by

$$V = \frac{100 \times s_M}{M} \text{ per cent} \qquad (6)$$

2. For a series of N values, each of which is the difference of two such titers $(A_i - B_i)$, e.g., on blank and unknown solution, respectively, we have

$$s^2_{(A-B)} = S_A^2 + s_B^2 \qquad (7)$$

provided $N_A = N_B$ or that they differ by an amount which is negligible.

3. Given p series of data, each comprising N_1, N_2, --------, N_p titrations, respectively, and each possessing a mean and standard deviation $(M_1 \pm s_1)$, $(M_2 \pm s_2)$, -------- $(M_p \pm s_p)$, respectively. Then, for a pool of all the data we can calculate the same statistics by the following equations:

$$N = \sum_{i=1}^{p} N_i \qquad (8)$$

$$M = \frac{\sum_{i=1}^{p}(N_i \times M_i)}{N} \qquad (9)$$

$$s^2 = \frac{\sum_{i=1}^{p}(N_i s_i^2) + \sum_{i=1}^{p}(N_i d_i^2)}{N} \qquad (10)$$

where $d_i = M_i - M$. If the several M_i values are in fairly good agreement, then d_i is negligibly small, and we have

$$s^2 = \frac{\sum_{i=1}^{r}(N_i s_i^2)}{N} \tag{11}$$

For a discussion of the application of statistical methods to problems of chemical analysis, the reader is referred to an article by Power.[8] For a more detailed and rigorous, though elementary, treatment of these methods see Rider.[9]

A SIMPLE AND RELIABLE METHOD FOR THE DETERMINATION OF METHYL ALCOHOL AND FORMALDEHYDE IN THE AIR*

C. F. Ackerbauer, B.S., and R. J. Lebowich, M.D., Gloversville, N. Y.

IN THE COURSE of an investigation upon the clinical effects of methylation in workers engaged in the tanning industry, it became necessary to determine accurately the percentage of formaldehyde and methyl alcohol vapors in the air. In this paper, the word "methylation" is used to indicate a direct union or substitution of the methyl radical in certain chemical compounds in the tissue cells and body fluids. Nearly all the chemical methods which have been proposed for their estimation have been based upon the principle of a solution of these gases in water or some organic solvent.

The method submitted was developed to substantiate the cause of possible injurious effects found clinically in workers in industries employing formaldehyde or its derivatives and methyl alcohol. In recent years the use of these products has increased tremendously due to their employment in the manufacture of plastics, disinfectants, adhesives, textiles, rubber, and paper.

A critical and exhaustive survey of the literature failed to reveal the existence of any technical method for the accurate estimation of formaldehyde and methyl alcohol in the air, the necessity of which is patent.

Zhitkova[2] in his article on the determination of poisonous vapors in the atmosphere, mentions a method for the detection of these gases. These procedures have been carefully followed, checked and discarded because they did not yield reproducible results with a high percentage of accuracy.

Wright[1] investigated numerous proposed tests for the determination of methanol depending upon its oxidation to formaldehyde. He states: "As oxidizing agents hydrogen peroxide, chromic acid, ammonium persulphate, hot copper spiral and potassium permanganate were tried, but all except potassium permanganate were rejected as unsatisfactory." These findings have been confirmed by us. Rosaniline, identical with Schiff's reagent modified, proved to be the most sensitive and stable reagent and yielded the most reliable and reproducible results. It was necessary to modify this method slightly in order to differentiate between formaldehyde vapors and those of methyl alcohol. The commercial use of formaldehyde fully embraces the use of methyl alcohol because, as manufactured at present, it contains 1 to 8 per cent of methyl alcohol, according to specifications, in order to prevent the possible polymerization of formaldehyde to paraformaldehyde.

Adaptation of the modified Schiff's reagent required the forced solution of formaldehyde and methyl alcohol vapors into an aqueous solution, eliminating other fumes which might cause interfering chemical reactions, thereby markedly invalidating the accuracy of the method. In the field, chlorine, sulfur dioxide,

---

*From the Eugene Littauer Memorial and Fulton County Laboratory, Nathan Littauer Hospital, Gloversville.

Received for publication, June 26, 1942.

formic and acetic acid fumes reacted with the reagents in the receivers, destroying the formaldehyde condensation violet color formed by the union of rosaniline and formaldehyde. Therefore, it was essential to develop an apparatus for the absorption of these gases from the air.

The method satisfied the following criteria: (1) Complete absorption of the vapors of formaldehyde and methyl alcohol present in a measured volume of air with their negligible condensation upon the walls of the vessels containing the absorbing fluids. (2) Regulation of their rate of diffusion and absorption. (3) Complete elimination of interfering and extraneous gases.

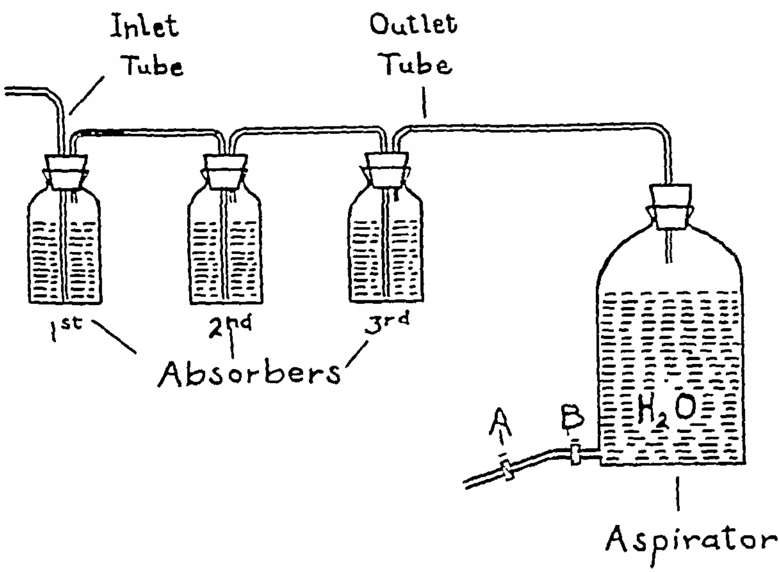

Fig. 1.—*A*, Screw clamp (snap). *B*, Screw clamp (variable).

DESCRIPTION OF APPARATUS AND ABSORBING SOLUTIONS

For routine analysis an apparatus was constructed according to Fig. 1. The gas absorbers consist of three stock laboratory bottles fitted tightly with a two-holed rubber stopper. One hole of each stopper accommodates a ¼ inch diameter glass inlet tube extending to within ⅛ inch from the center of the bottom of the bottles. The other hole accommodates a ¼ inch diameter glass outlet tube which extends ¼ to ½ inch below the bottom of the stopper.

The bottles are so arranged in a series of three that the first inlet tube is joined to a glass tube of ½ inch diameter. The last outlet tube is connected to a 5 liter glass aspirating flask, the outlet of which regulates the flow and volume of the test sample of air through the system. Two screw clamps serve as valves to adjust the flow of water from the aspirator; one is permanently set to insure the same rate of flow for successive determinations; the other acts as a shut-off for the entire system. The diameters of the inlet openings are adjusted to a 1.6 mm. aperture to allow only small bubbles of the incoming vapors to pass through the liquids in the absorbers in a steadily flowing stream. Larger openings would permit the passage of excessively large bubbles carrying traces of impurities of sulfur dioxide, chlorine, and carbon dioxide, and these represent a source of considerable technical error. The use

of aerator stones was investigated and determinations with them proved inaccurate. They introduced a phenomenon of selective adsorption which did not remain constant throughout the period of time necessary to conduct a test.

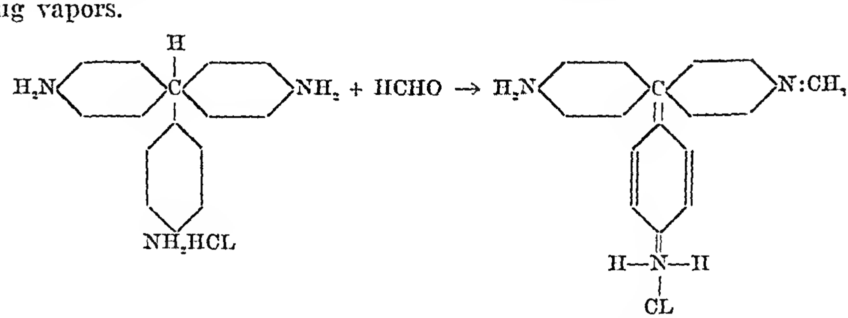
After many experiments the following solutions and their indicated concentrations were selected for the absorption of the interfering vapors and those to be estimated.

The first absorber containing 150 c.c. of a 1 per cent phosphoric acid and 2 per cent barium chloride solution in equal amounts removes all the sulfur dioxide fumes and the formic and acetic acid vapors. Frequent check tests were made on this solution to determine the amount of formaldehyde and methyl alcohol vapors absorbed, and the results revealed their presence only in minute negligible traces. This fact is believed to be due to the property of formaldehyde and methyl alcohol being more unstable in an acid solution than in an alkaline solution. The mild state of aeration tends to influence the presence of formaldehyde and methyl alcohol as a gas. The carbon dioxide, as it passes through water, forms carbonic acid, which reacts according to the following equation. The phosphoric acid acts as a carbonic anhydrase, as first purified by Meldrum and Roughton.[3] This accelerates the reaction in both directions: $H_2CO_3 + BaCl_2 \leftrightarrows 2HCl + BaCO_3\downarrow$.

The second absorber contains 200 c.c. of an alkaline solution of 5 per cent potassium permanganate, which completely removes by oxidation all the methyl alcohol.

The third absorber contains 225 c.c. of modified Schiff's reagent, and the fourth, employed for experimental purposes, holds 200 c.c. 2 N sodium bisulfite solution.

The errors introduced by the entrainment of formaldehyde vapors into the first and second absorbers were found to be 1 part in 1,000 in the first absorber and 3 parts in 1,000 in the second absorber. In the third absorber, over 97 per cent of the formaldehyde vapors react with the modified Schiff's reagent, according to the following supposed equation forming the characteristic Schiff's violet color,[1] the intensity of which is proportional to the amount of reacting vapors.



The fourth experimental absorber, although unnecessary, was used to detect any escaping formaldehyde vapors by their reaction with sodium bisulfite solution, forming oxymethyl sodium sulfonate, according to the equation:

$$HCHO + NaHSO_3 \rightarrow H_2C\begin{cases} OH \\ SO_3Na \end{cases}$$

In some instances, volumes of vapors as high as 3.5 per cent were noted under conditions where the temperature of the surrounding atmosphere was above 80° F.

DESCRIPTION AND RATIONAL OF METHOD

By means of the variable screw clamp, the vacuum created by the flow of water is regulated so that one liter of water flows freely without pulsations every twenty-five minutes. It is absolutely necessary that pulsations be eliminated, because many large bubbles may be forced spasmodically through the absorbers so rapidly that they may carry with them entrained vapors which are not absorbed in their respective solutions.

In order to absorb completely all the formaldehyde and methyl alcohol vapors, as well as to remove all interfering gaseous substances, it is necessary to allow at least 1 liter of water to flow from the aspirator. By experimentation with the object of reducing the percentage of technical error in the method to a minimum, it was found that the use of 5 liters of water yields very accurate results, but a volume of 5 to 10 liters is even more reliable and, therefore, desirable, as shown in Table II.

In a routine analysis, 1,000 c.c. of vapors are allowed to pass through the system in order to remove the air above the surface of the liquid in each absorber and saturate it with the vapors to be expelled from that solution. One liter of water is permitted to flow from the aspirator for a period of twenty-five minutes, and then its flow is stopped by the second snap clamp. The level of water is again adjusted in the aspirator and another 1,000 c.c. of air are inducted. While the aspirator is being filled, a vent must be opened or the liquids in the absorbers will be forced backward through the system, thus invalidating the results. This is repeated until at least 5,000 c.c. of air have been drawn through the receivers.

Absorbers 2 and 3 are removed, sealed with a rubber stopper, and are brought to the laboratory. To repeat the determinations, it is only necessary to renew the liquids in absorbers 2 and 3. The liquid in absorber 1 is sufficiently concentrated to be employed for at least ten determinations without renewal.

In the laboratory, the procedure for the analysis of the solutions in absorbers 2 and 3 is followed according to that outlined by Wright.[1] The potassium permanganate solution is decolorized with the oxalic-sulfuric acid solution and then the modified Schiff's reagent is added. Color comparisons are made with standards already set up and are matched with the naked eye, or preferably with a Hellige colorimeter.

Comparisons were made with the photoelectric colorimeter but were found to be unreliable, due to the inability of the photoelectric cell to differentiate between different wave lengths in the red and blue zones as well as to the intensity of these colors.

If the fourth absorber is used, the per cent of formaldehyde gas is determined volumetrically, using rosolic acid as an indicator, according to the equation:

$$HCHO + Na_2SO_3 + H_2O \rightarrow NaOH + NaSO_3 + (H_2COH)$$

In the field it was found that absorber 4 could be eliminated without seriously affecting the results.

Table II shows the results of the experiments conducted in a room, the known composition of its air being assumed to be 14 parts per 100,000 of HCHO and 0.6 parts per 100,000 CH_3OH. This assumption is based upon the fact that the possible condensation and adsorption of the vapors on the walls of floor and ceiling of the rooms and containers are negligible. Another assumption is that the rate of diffusion of these vapors becomes a constant after three to four hours. The tests show the effect of the rate of flow of 1 liter of air through the system in the period of time designated. All tests were conducted with the temperature maintained at 70° F.

TABLE I

TEST	TIME (MINUTES)	ABSORBER 2 CH_3OH (P.P.M.*)	ABSORBER 3 HCHO (P.P.M.)	ABSORBER 4 HCHO (P.P.M.)
1	5	Trace	Trace	4
2	10	Trace	Trace	10
3	15	Trace	10	60
4	20	Trace	50	50
5	25	1	128	10
6†	30	1	140	5

*Pulsations occur because the water did not flow freely but in drops.
†p.p.m. = parts per million.

TABLE II

TEST	VOLUME IN LITERS	ABSORBER 2 (P.P.M.)	ABSORBER 3 (P.P.M.)
1	1	1	130
2	3	1.5	132
3	5	5	140
4	10	7	148
5	12	6	150
6	15	7	149

Intervals of twenty-five minutes were decided upon for the period of the rate of flow. Table II shows the results of the experiments using the rate of flow of 1 liter of air for twenty-five minutes under the same previous existing conditions and with an increase of the volume of air passing through the absorbers before the laboratory tests are performed.

If the larger volumes of air are used, the intensity of color makes comparison with the standards more difficult to match with accuracy. It was also found that some vapors would escape through the aspirator, thus demonstrating that under these conditions the solutions in the absorbers had become saturated.

Table III shows the results of the experiments using the same standard conditions previously stated and varying the height of the inlet tube from the floor.

TABLE III

TEST	HEIGHT OF INLET TUBE FROM FLOOR IN FEET	ABSORBER 2 (P.P.M.)	ABSORBER 3 (P.P.M.)
1	1	20	100
2	3	8	180
3	5.5	3	160
4	7	1	80
5	10	1	30

A sealed room with temperature controlled at 70° F. was used for obtaining results shown in Table III. Vapors were introduced at a point as near the middle of the room as possible. This more closely resembles conditions as found in the field analysis. Although most of the material remain at the floor level, the height where the solutions have a greater tendency to vaporize would be around 5 feet.

These results show the effect of diffusion upon the vapors of CH_3OH and HCHO in the air in a room after three to four hours. The height 5.5 feet was selected as the average height of a person present in a work room. The results of Table III also demonstrate the percentage of vapors in a room at this height where workmen might inhale or come into contact with these vapors.

SUMMARY

A simple and reliable method is submitted for the estimation of methyl alcohol and formaldehyde vapors in the air, employing the modified Schiff's reagent of Wright, and having a possible technical error up to 7 per cent.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor, Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

A Manual of Allergy*

THE author explains the writing of this book in the fact that while there are satisfactory large texts on the subject for the use of allergists, and while there are popular books through which the layman can understand allergy, there is need for an intermediate volume which will serve the medical man whose interest is only secondary and who does not wish to burden himself with extensive reading of the larger volumes.

Dr. Cohen's many important contributions to the subject give to his writings a generally recognized authoritativeness.

The book is well written and covers the subject excellently to the extent that general practitioners and nonmedical persons as well can gain a clear understanding of the processes of allergy. One is left with the feeling that Dr. Cohen would have done well to have enlarged it a little more with detailed discussion of the routines of specific diagnosis and treatment. One who has read the book and desires to proceed with allergic studies must still refer to the larger volumes. Although it would be desirable to have it all in one book, there is justification for the author's plan of presentation, in that those who actually wish to use allergic procedures should become acquainted with intricate details as well as with general principles. This certainly should make for better allergic practice.

In this sense we might consider the present volume as an Introduction to Allergy.

An Atlas of Human Anatomy†

TOLDT'S *Atlas of Human Anatomy*, first published in this country in 1919, has gone through two editions and four printings. This no doubt accounts in part at least for the surprisingly reasonable cost of the latest printing. The volumes consist almost exclusively of plates, each of which contains duplicate Latin and English terminologies. Division into two volumes makes for easy handling. Although the sequence of plates is that commonly used in most anatomies, beginning with bones, joints, and muscles, and ending with the nervous system and special senses, the sequence continuity is more logical than in some other texts, facilitating progression from one area to a neighboring one. This is especially illustrated in the muscles of the lower extremities.

Internal Medicine in Old Age‡

INTERNAL MEDICINE IN OLD AGE can be divided roughly into two parts: the first, a short survey of the nature and problems of aging and old age; the second, a comprehensive review of the clinical and diagnostic features and therapeutic management of those

*A Manual of Allergy—For General Practitioners. By Milton B. Cohen, M.D., Director of the Asthma, Hay Fever, and Allergy Foundation; Visiting Physician in Allergy, St. Alexis Hospital, Cleveland, Ohio. Cloth, 156 pages, $2.00. Paul B. Hoeber, Inc., Medical Book Department of Harper & Brothers, New York and London, 1941.

†An Atlas of Human Anatomy. For students and physicians. By Carl Toldt, M.D. Assisted by Professor Alois Dalla Rosa, M.D. Adapted to English and American and International Terminologies by M. Eden Paul, M.D. Brux., M.R.C.S., L.R.C.P. Vol. I. New second edition containing sections on Regions of Human Body, Osteology, Arthrology, Myology (Figures 1 to 640, and general index to the two volumes), 390 pages. Vol. II. New second edition containing sections on Splanchnology, Angeiology, Neurology, Organs of the Senses (Figures 641 to 1505, with appendixes and general index to the two valumes.) Cloth, copyright 1919. Reissued in two volumes, June, 1926. Reprinted January, 1941. The Macmillan Company, New York.

‡Internal Medicine in Old Age. By Albert Mueller-Deha ... Physician, ... hronic Disease (Second Divisio ... New York ... Professor of Internal Medicine, ... School, an ... ision, ... S. Milton ... Profe ... School, Col ... ave): Cloth, 396 pages, $5.00. A William Wo ... more, 1942.

diseases most common in the late decades of life, as well as of diseases more common in early years which present special problems in the aged.

The book should be of great value to those who desire an introduction to the field of geriatric medicine, as well as to those practicing physicians who desire ready reference to the pictures presented by disease in the aged. It is simply written and well-documented. The authors' practice of including a liberal number of thumbnail case histories adds interest to the reading and emphasis to the text, underlining the thesis that diagnosis of disease in the aged presents special problems, is not to be undertaken without mature reflection, and is, in spite of all, often mistaken or missed.

Internal Medicine in Old Age offers a wealth of therapeutic suggestions. Nothing seems omitted which might bring relief to the patient. There are valuable suggestions concerning nursing technique as well as chemotherapeutics. The reviewer recommends the book to student and practitioner alike as a valuable and timely review of geriatric medicine.

Clinical Pellagra*

LIKE the period at the end of a paragraph this book punctuates an epoch in the study of pellagra. Dr. Harris starts his discussion with a comprehensive historical review of the early recognition and incidence of the disease, and the early theories as to its causation. This makes interesting reading. Next is a summary of the experimental investigations, those preceding vitamin studies and the vitamin studies themselves.

The major portion of the book is devoted to present knowledge of the etiology, pathology, symptomatology, diagnosis, prognosis, and treatment of the disease. The chapter on Prophylaxis is especially important.

Collaborating contributors from the several institutions, especially in the South, where constructive research has been carried out, have written chapters on the work done in these institutions.

Here we find in a single volume all that need be summarized concerning pellagra.

Laboratory Diagnosis of Protozoan Diseases†

COLONEL CRAIG'S manual of laboratory methods for the diagnosis of diseases caused by protozoan organisms is especially appropriate at the present time when, with American forces in tropical climates, the problem of protozoan infection bids fair to become extremely important. Somewhat over a third of the book is devoted to amebic infection and considerable space is also given to malaria. The remainder of the book deals with the other common tropical infections, as well as protozoan infestations commonly seen in the United States, such as the flagellate infections.

The volume will undoubtedly be widely read.

The Principles of Neurological Surgery‡

THE second edition of Davis' *Neurological Surgery*, like the first, contains full discussion not only of neurological procedure but also of neurologic diagnostic methods. For this reason, it will be useful both to surgeons and to neurologists and internists.

*Clinical Pellagra. By Seale Harris, M.D., Professor Emeritus of Medicine, University of Alabama, Birmingham, Ala. Assisted by Seale Harris, Jr., M.D., formerly Assistant Professor of Medicine, Vanderbilt University, Birmingham, Ala.; with Foreword by E. V. McCollum, Ph.D., Sc.D., LL.D., Professor of Biochemistry, School of Hygiene and Public Health, the Johns Hopkins University, Baltimore, Md. Cloth, illustrated, 494 pages. The C. V. Mosby Company, St. Louis, 1941.

†Laboratory Diagnosis of Protozoan Diseases. By Charles Franklin Craig, M.D., M.A. (Hon.), F.A.C.S., F.A.C.P., Colonel, United States Army Medical Corps, Retired D.S.M. Emeritus Professor of Tropical Medicine, Medical School, Tulane University; Member, American Academy of Tropical Medicine, American Society of Tropical Medicine, American Society of Parasitologists; Honorary Member, American Society of Clinical Pathologists, etc. Cloth, illustrated with 54 engravings and 4 colored plates, 349 pages, $4.50. Lea & Febiger, Philadelphia, 1942.

‡The Principles of Neurological Surgery. By Loyal Davis, M.S., M.D., Ph.D., D.Sc. (Hon.), Professor of Surgery and Chairman of the Division of Surgery, Northwestern University Medical School, Chicago, Ill. Cloth, ed. 2, thoroughly revised with 154 engravings and 298 illustrations and 5 colored plates, 503 pages, $7.00. Lea & Febiger, Philadelphia, 1942.

Biological Symposia*

BIOLOGICAL SYMPOSIA comprises four symposia arranged by the Council of the American Society of Biological Chemists for the Chicago meeting of the Federation in April, 1941. The following subjects of current interest are discussed by authorities in each field:

End Products of Nitrogen Metabolism in Plants; End Products of Nitrogen Metabolism in Animals; Merging of Growth Factors and Vitamins; The Oxidation of Branched-Chain Fatty Acids; The Origin and Regulation of Ketone Bodies from Fats; The Anabolism and Function of the Phospholipids; The Formation of Animal Body Fat. Oxidation Catalysts; Phosphorylation of Glycogen and Glucose; Oxidoreductions in Carbohydrate Breakdown; Pyruvate Oxidation and the Citric Acid Cycle. Choline, the B Vitamins and Fat Metabolism; The Relation of Choline to the Kidneys; The Nature and Significance of Cholinesterase; Interrelationships Between Choline and Other Methylated Compounds.

Textbook of Embryology†

NOT even embryology has reached a static stage in medical science. Jordan and Kindred's fourth edition has quite a number of changes from the third edition. New subjects include embryonic hormones, the *in vitro* development of mammalian embryos, transplantation, and extirpation experiments designed to reveal differential potencies of different portions of the blastoderm, results of administration of growth and sex hormones, and results of restriction of vitamins. There are 78 new illustrations.

The Conquest of Bacteria‡

A "POPULAR" exposition is *The Conquest of Bacteria*, which can be commended for the general reader, especially because, as stated by Sigerist in the Foreword, it tells the story of chemotherapy in simple and sober terms. It is interesting and informative. A safe book for the public.

A Manual of Endocrine Therapy§

THE *Manual of Endocrine Therapy* might at first glance give the impression that the author is unduly optimistic about the results in too wide a variety of maladies. In the Summary of Therapy, Chapter 15, we find such subjects as acne, dysmenorrhea, enuresis, frigidity, and homosexualism, with a listing of the appropriate endocrine medications and dosage. However, when one turns to the body of the small book he finds that Dr. Cinberg's discussion of these and similar subjects is adequately critical. In other words, in the summary he presents the recommendations of others, many of which he himself has found to be unwarranted. This is a handy, quick reference manual for therapy which can be well recommended. It is unfortunate that there has been an error in the index so that in most cases the subject referred to appears on the page following that indicated by the index.

SYMPOSIUM ON WAR MEDICINE. I.

Guest Editorial

THE PROFESSION'S WAR RESPONSIBILITY

Colonel James M. Phalen, Editor, The Military Surgeon

IT WAS with a sharp note of dissatisfaction and of warning to the medical profession of the country that Mr. Paul V. McNutt, Chief of the War Man Power Board, spoke to a session of the American Medical Association at its Atlantic City meeting in June, 1942. In direct and unequivocal terms he stated that the voluntary program for meeting the medical needs of the armed forces and of war industries had been a failure, and that unless the plan produced greatly improved results within a short period "a more vigorous plan," presumably the draft of medical personnel, would have to be put into operation.

Following the statement that the needs of the Army and Navy for medical officers were not being met, he said that it was apparent that the "careful safeguards" that had been set up by the Association's Procurement and Assignment Service had slowed down the rate of recruitment of doctors for the services. If this be indeed so, it is an example of a miscarriage of well-laid plans. The program for procurement and assignment was the result of diligent and well-considered planning by thoroughly competent men. It was calculated to feed medical officers into the armed services as they were needed, to provide skilled attendance to workers in the war industries, and to guarantee that the civilian population should not be deprived of medical attendance. The functions of the agency were of necessity decentralized, the unit of administration being a state board. Why these theoretically perfect plans have not produced the results expected is difficult to say. Mr. McNutt did not elaborate upon his general indictment of the "careful safeguards" of the Association program. The criticism would indicate an undue solicitude for the wants of the civil population.

The speaker charged a marked difference in the enthusiasm of doctors for voluntary service between the war of 1917-1918 and the present conflict. The figures that he gave for voluntary inductions into the services during comparable periods of the two wars, if they could be accepted as wholly valid, would constitute a keen indictment of the present generation of physicians. But conditions were by no means the same and really just comparisons are not possible. There have been, however, very convincing evidences of reluctance of eligible physicians to enter the military services. The lowering in 1940 of the draft age from 34 to 28 years was quickly followed by a marked drop in voluntary inductions of physicians who would otherwise be subject to the draft. The restoration of the former age limits acted as a distinct spur to recruiting.

We cannot question Mr. McNutt's statement that recruitment of the medical profession had not been satisfactory. He said that 5,000 additional doctors were needed before the end of June, 1942, and 20,000 more before the end of the year. These figures give a vivid picture of an acute recruitment problem. The estimate was made that it would take one-third of the physicians of the country to meet the needs of the armed services and that this would embrace two-thirds of those under the age of 45 years.

Dr. Fred W. Rankin, the incoming president of the Association, could only agree with the main items of criticism and that the profession had a definite responsibility in the allotment of its services in this time of emergency. He cited the progress that was being made in bringing back into active practice a great number of retired or semiretired physicians, thus making possible the release for military service of many otherwise indispensable practitioners of younger years.

The basic fact is that there are not enough doctors in the country for essential services. Like sugar and gasoline, they must needs be rationed. The task of this rationing was assigned to the Procurement and Assignment Service, which is now under criticism. The voluntary features of this plan will be followed until they are found definitely lacking. Only then can we look for the rationing to fall into other hands and the "more vigorous plan" put into effect.

THE ROLE OF CONTEMPORARY MEDICINE IN THE CURRENT WAR EFFORT

Lieut. Col. Joseph Rogers Darnall, M.C., U. S. Army

As CIVILIZATION staggers painfully through the kaleidoscopic tragedy of another World War, the characters in this great drama emerge and assume their destined roles. Medicine is honored with an heroic but difficult part in this colossal play, and proper performance is essential if the Axis villain is to be destroyed and the drama is to end happily.

This is by no means the first time that medicine has served humanity by playing a beneficient part in the promulgation of war. Since the days of Moses, the first great sanitarian, civilizations have risen and fallen as a result of the influence of disease upon military campaigns.

While inventive genius throughout the ages has perfected deadlier weapons, so also the minds of men have devised more effective protective measures to preserve the human race. The ever-increasing strength of scientific medicine provides a powerful bulwark against the rising tide of destructive warfare which is sweeping over the world today.

It is not my intention to review the medical accomplishments of former years other than to mention briefly a few of the outstanding achievements since 1914, and then to outline the contributions that are now being made by medicine toward the successful prosecution of the war. Many medical contributions to the current war effort would be impossible were it not for the advances in medicine which occurred during previous military conflicts or as a result of them.

During Kaiser Wilhelm's bloody bid for immortality in those hectic years of 1914-1918, preventive medicine climbed to new heights. Standardized methods of controlling and treating venereal diseases, initiated by the United States Army in 1909, were developed on a large scale in 1917. The undisputed value of typhoid vaccine and of tetanus antitoxin was established beyond doubt as a result of the experience of World War I. The cause of that great louse-borne scourge, trench fever, was discovered, and the control of this important war disease which sapped the fighting strength of great armies was accomplished. Following the Armistice, the determined attack of American medicine on typhus fever in Serbia and Poland demonstrated the usefulness of intensive educational campaigns as a means of controlling communicable disease.

The first World War also stimulated progress in air-conditioning, in rat-proofing, and in aviation medicine. In general, there was an enormously increased dissemination of knowledge concerning hygiene and sanitation, and a healthy expansion of clinical activities in the field of public health following the Armistice of 1918.

Internal medicine gained ground as a result of experience acquired on the battlefields and in the hospitals and laboratories a quarter of a century ago. Extensive investigation of respiratory diseases was stimulated by the pandemic of influenza. As the years unfolded, the laboratory segregated and subdivided the numerous pneumococcus pneumonias. During World War I a therapeutic antitoxic serum was developed to combat the dreaded gas gangrene. The problems and vast experience of that war spurred neuropsychiatry to greater knowledge, and better care for the victims of permanent psychoses was encouraged. Fever therapy of neurosyphilis was inaugurated when the malarial blood of two "shell-shocked" German soldiers was injected into the veins of paretic patients with encouraging results.

"Functional" disorders of the heart and of the neurovascular mechanism became conspicuous during the war. Later, as time relentlessly rolled by, veterans with degenerative cardiovascular disease presented themselves for treatment at government hospitals in ever-increasing numbers, thus focusing attention on those "middle-age" maladies which have made the profession more "coronary conscious."

Little need be said of the well-known contributions of World War I to the advancement of surgery. Battle casualties provided a vast clinical material which resulted in improved surgical knowledge and technique. Mention should be made, nevertheless, of the improved management of orthopedic cases, the Orr method of treating compound fractures, revival of debridement, and development of the Carrel-Dakin technique. The war gave birth to thoracic surgery and produced improved treatment of empyema, shock, osteomyelitis, and septic arthritis, to say nothing of the great gains made in faciomaxillary and plastic surgery, or of improvements in the suturing of blood vessels and nerves.

Physical therapy and occupational therapy were infused with life and became useful adjuncts of orthopedics and neuropsychiatry during and following the Kaiser's war to impose Teutonic Kultur upon an unwilling world.

It cannot be denied that military resistance to German aggression in 1914 also brought contributions in the field of medical organization, education, and literature. The examination of conscripts then, as now, drew public attention to the lack of physical and mental fitness and focused thought on the interrelated problems of medicine, economics, and sociology. The war showed medicine the value of teamwork and logical division of labor, so that specialization developed and group practice flourished when peace came.

Although much may be said concerning the contributions of war to the advancement of medicine, we are at present more vitally concerned with what medicine can contribute to successful prosecution of the war and a United Nations' victory.

With justifiable pride it may be pointed out that the medical departments of our armed services were not caught napping when the Japanese struck at Hawaii and the Philippines on Dec. 7, 1941. Long before that fateful date medical plans had been laid and preparations made to meet such an eventuality.

The advent of selective service training in 1940 signalized important developments in the mobilization of American medicine for war. These develop-

ments may be briefly summarized as follows: Beginning in June, 1940, at the request of the Surgeons General of the Army, Navy, and Public Health Service, the American Medical Association undertook a survey of the physicians of the United States, with special reference to their qualifications and availability. This was accomplished under the direction of the Committee on Medical Preparedness of the American Medical Association.

A total of more than 185,000 physicians received questionnaires from this Committee and by Jan. 2, 1942, more than 158,000, or nearly 86 per cent, had returned them. Considering the average physician's instinctive avoidance of paper work and hostility to questionnaires, this response of the profession was indeed a tribute to the cooperative spirit of American medicine in furthering the war effort.

Thus the foundation was laid for the establishment of the Procurement and Assignment Service for Physicians, Dentists, and Veterinarians on Oct. 30, 1941. This service, which is now under the War Manpower Commission, was established by the President as one of the subdivisions of the Office of Defense Health and Welfare Service. Another subdivision of the Office of Defense Health and Welfare Service is the Health and Medical Committee, which occupied adjoining offices and collaborated closely with the Procurement and Assignment Service. This Health and Medical Committee was first established on Sept. 19, 1940, by the Council of National Defense, "to advise the Council of National Defense regarding the health and medical aspects of National Defense and to coordinate health and medical activities affecting National Defense."

When, on Sept. 3, 1941, the President set up the Office of Defense Health and Welfare Service with Mr. Paul V. McNutt as Director, the Health and Medical Committee was transferred to that office. This committee deals with the more general aspects of medicine's participation in the war effort through its subcommittees on Dentistry, Hospitals, Industrial Health and Medicine, Medical Education, and Negro Health.

One of the first agencies to assist the Surgeons General of the Army, Navy, and Public Health Service in the current war effort was the Division of Medical Sciences of the National Research Council of the National Academy of Sciences. More than 40 committees and subcommittees, covering practically every field of medicine, were organized in 1940. These committees included more than 200 physicians, eminent in their various specialties.

The National Academy of Sciences was established by President Lincoln in 1863, under a Congressional charter which stipulated that the Academy, whenever called upon, should advise the government on any subject of science or art. It is significant that the need for such a scientific advisory body was keenly felt as long ago as the War Between the States.

The National Research Council of the Academy is composed of nine divisions, one of which is the Division of Medical Sciences. No less than 17 national societies of medicine and allied sciences are members of the Division of Medical Sciences.

The Division of Medical Science committees of the National Research Council do not duplicate the activities of the Health and Medical Committee of the

Defense Health and Welfare Service. The latter covers the more general aspects of health and national defense, while the National Research Council committees are called upon, as quasi-governmental agencies, for special professional advice and research.

Anticipating the likelihood of disease epidemics arising as a result of military mobilization, the Surgeon General of the Army, on Dec. 27, 1940, proposed the establishment of a "Board for the investigation and the control of influenza and other epidemic diseases in the Army." The creation of this board was approved by the War Department on Jan. 11, 1941, and the Surgeon General proceeded to organize the board by the assignment of a number of distinguished civilian consultants, each appointed by the Secretary of War.

The board is composed of (1) a central advisory group of seven members and (2) eight investigative commissions concerned primarily with the following eight problems: influenza, meningitis, measles, neurotropic virus diseases, streptococcus diseases, epidemiological surveys, pneumonia, and cross infections.

It may properly be deduced from the afore-mentioned steps to insure collaboration with the best civilian medical talent, that the medical departments of the armed services were keenly alert to the need for medical preparedness. The response of the profession in cooperating with the military by early organization of useful medical agencies to assist the preparedness program has been excellent.

The role of contemporary medicine, however, is not confined to *civilian* participation in the current war effort. It embraces also the organization and activities of the medical departments of our armed forces, which are primarily concerned with furnishing medical service to the Army and Navy. The mission of these medical departments is "to conserve fighting strength," and "to keep as many men at as many guns as many days as possible."

The principal part played by medicine in the first act of the drama of war was the selection of suitable military personnel by excluding from the armed services the physically and mentally unfit. This called for the formulation of appropriate physical standards, and the judicious interpretation of these standards by the thousands of physicians, civilian and military, who were called upon to accept or to reject volunteers for enlistment and selectees for induction.

In the second act of the military drama, medicine plays the part of a guardian angel. In this role, through the application of modern principles of sanitation and disease prevention, medicine protects against pestilence and strives to keep the military personnel, as well as industrial workers, in good physical condition.

In the third act of the war drama, tragedy is the keynote, and medicine appears as the healer of wounds and disease. The unfortunate participants, military and civilian, who become disabled must be furnished with such aid in the form of evacuation and hospitalization as will speedily restore them to health and fighting efficiency, so that the show may go on to the fourth and final act in which medicine assumes another major role in the rehabilitation of the disabled and in the reconstruction and stabilization of civilization. This last act is interminable and the curtain is never run down!

If American medicine is to accomplish its wartime mission, physicians must make great sacrifices as in 1917-1918. Since Pearl Harbor many medical veterans of World War I have developed "itching feet" and have been clamoring for another "hitch" of active duty. Many of them are now in uniform, and others, whose patriotism is unassailable, are "chafing at the bit." But active military service is largely a *young man's* game, and most of those who did their bit so magnificently in World War I, *when they were young men,* may now serve their nation best by guarding the home front.

Meanwhile, let the young physicians continue to come forward and fill the many positions in which their services are so sorely needed in the Army. These positions include not only professional assignments in hospitals and dispensaries, but also duties with tactical units. In time of combat each military unit the size of battalion or larger must be served by medical officers.

Field medical service, to be effective, requires adequate personnel to man the aid stations and unit dispensaries; to supervise evacuation of casualties; to establish and render professional service at collecting stations and clearing stations; to staff mobile surgical hospitals, evacuation hospitals, convalescent hospitals, field laboratories, and field medical supply installations.

Behind the combat zone in theaters of military operation, as well as in the zone of interior, medical men are needed at air fields, on hospital trains, at station hospitals, general hospitals, convalescent camps, dispensaries, laboratories, medical supply depots, and training centers; and to form medical personnel replacement pools, as well as for service with medical detachments assigned to tactical combat units.

The wide dispersion of our Army throughout the world requires proportionately more medical personnel than would be needed if our troops were concentrated in one principal theater of military operations, such as occurred in World War I. It is the responsibility of American medicine to see that these necessary personnel are made available.

The role of contemporary medicine in the current war effort is, indeed, a role of utmost importance which carries a responsibility of great magnitude. It calls for the maintenance of the health of civilian populations, especially industrial workers, and it demands adequate care for the health of our Army and Navy at home and abroad, for this is a war of annihilation or survival. Without conservation of our fighting strength we cannot hope to preserve civilization.

THE ARMY'S MEDICAL FIELD SERVICE SCHOOL AND ITS WAR TRAINING OF MEDICAL OFFICERS

COLONEL EDGAR ERSKINE HUME, MEDICAL CORPS, U. S. ARMY
CARLISLE BARRACKS, PA.

THE most extensive and most important work in the training of American medical officers for field duty in the present war is being done at the Medical Field Service School at Carlisle Barracks, Pa. At one of the Army's oldest and most historic posts there are being trained thousands of medical, dental, veterinary, sanitary, and medical administrative officers for the greatest war effort our country has ever had to put forth. Under the pressure of necessity, the efforts of a faculty of selected officer instructors are bent toward giving as much field training to as many officers as the military situation permits. We have many medical men in service. We need many more. Training goes on without cease, for there is ever the consciousness that no amount of money, no gifts of a generous and frightened Congress can buy us yesterdays. We have everything now needed to create a winning Army, save time. But even without as much time as we should like we can do great things with the fine officers and men who are flocking into the Army's Medical Department. We can overcome even the handicap incident to curtailed periods of instruction and turn out the men who will play the Medical Department's role in the winning of the victory.

WHY SHOULD AN ARMY HAVE MEDICAL OFFICERS AND MEDICAL SOLDIERS?

An unthinking person may feel that the only duty of a medical officer of the Army is to treat the sick or wounded man when brought to him for that purpose. Were this true, the Army would need no medical service at all. It would merely be necessary to employ civilian physicians and surgeons from time to time whenever and wherever needed. It is to be feared that some medical men otuside the military service are of this opinion.

But, unfortunately, it is not so simple. The Medical Department has many functions, all of which grow out of its great task *To Conserve Fighting Strength*—words which constitute the motto of the Medical Field Service School. It is our duty to select for the military service only those men who are physically fit for the duties expected of them, and thereupon, having admitted them, to keep them fit. Preventive medicine, in other words, is more valuable to the Army than is curative medicine, important though the latter is. Wars are won by men and not merely by machines. No matter how highly developed become our aircraft, our tanks, our submarines, and the rest, it is the human factor in the end that wins or loses wars.

Morale is an intangible thing, but one of supreme significance to the soldier. It is like the temper in the Damascus blade. Soldiers with high morale win

through to victory. Soldiers of poor morale have lost the battle before it begins. This is especially true of the officers, for officers with low morale cannot inspire their men to do deeds of military valor. Everyone knows the old adage that an army of lambs led by a lion is better than an army of lions led by a lamb.

All this is by way of stressing the importance of the Medical Department in the maintenance of morale. Fighting men must feel that if they are wounded or ill they will receive adequate medical care. They are encouraged and heartened by the knowledge that the medical soldier and the medical officer will accompany them right into action. There is no place that the infantryman goes, for instance, that the medical soldier does not go. Officers of the line have a way of telling their men that when frightened—and all soldiers are frightened at times—it is a good idea to fire in the direction of the enemy. Somehow this renews courage. It is the good old American spirit of striking back. Even though the riflemen may know that the chance of his hitting one of the enemy is small, he is nonetheless cheered by his ability to strike a blow.

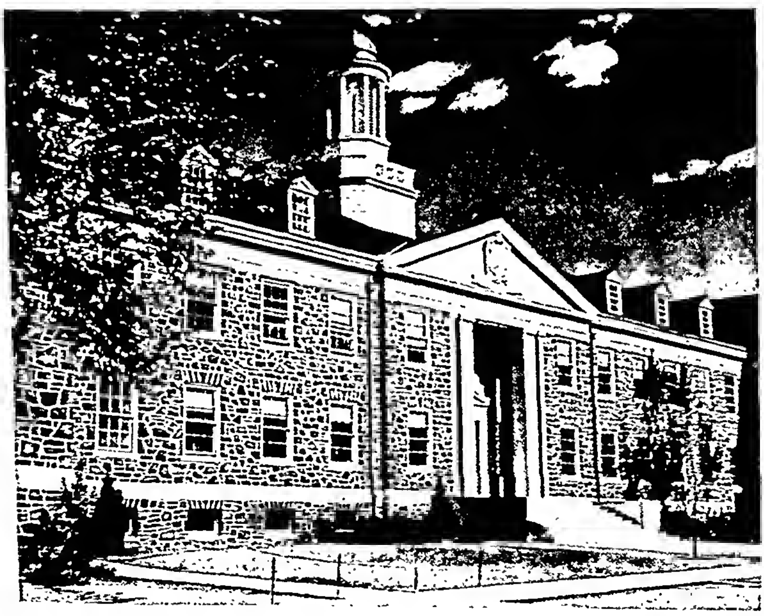

Fig. 1.—Hoff Hall, Medical Field Service School, Carlisle Barracks, Pa. Principal academic building. (Photograph by U. S. Army Signal Corps.)

But the medical soldier cannot do this. He is unarmed. His task is to care for the wounded men in action; he has no rifle with which to fire at the enemy. Only under rare conditions are medical soldiers armed; only, in fact, under the Geneva Convention, when it is necessary for them to defend wounded in their care. It takes a high order of courage for the unarmed man to stand up under the fire of the enemy and hold his ground. But that is exactly what our medical soldiers have always done.

Thus not merely from the humanitarian side is the Medical Department of the United States Army needed. As a morale builder it is a positive asset to the Commander-in-Chief. All this is taught the students at the Medical Field Serv-

ice School, but it is all predicated on our having thoroughly trained medical officers and men and military as well as medical training.

CARLISLE BARRACKS NOT A REPLACEMENT CENTER

The Medical Field Service School, Carlisle Barracks, is not a school for the training of medical soldiers; that is, enlisted men of the Army Medical Department. Its job is essentially one of training Medical Department officers, though a short course for selected noncommissioned officers is offered annually in time of peace. There are conducted, also, classes for enlisted Sanitary Technicians, of approximately one month each.

The task of Carlisle Barracks is "train the trainers." Many officers trained there are sent to the Replacement Centers where they assist in training the enlisted men. The Army maintains several such training centers: Camp Pickett, Virginia (formerly at Camp Lee, Virginia); Camp Grant, Illinois; Camp Barkeley, Texas; and Camp Joseph T. Robinson, Arkansas.

THE MEDICAL DEPARTMENT'S RECORD IN THE FIRST WORLD WAR

One may judge the future only by a knowledge of the past. We are engaged now in the most stupendous struggle that our land has ever known. Everything that we are and everything that we have is at stake. We at the Medical Field Service School are bending our every effort to impress upon the officers and officer candidates who take the various courses of instruction, the fundamental fact that they form an essential cog in the mighty military machine. They have before them the record of our service in other wars, particularly the first World War. Here are a few significant facts pertaining to that war:

> The first American wounded was a Captain of the Medical Corps; the second was an Army nurse. The first American killed was an enlisted man of the Medical Department. We have named one of our buildings Tugo Hall in his honor. The first American Army unit to reach Europe was a medical unit. The last to leave when we withdrew from the occupation of Germany was a medical unit. One may see the flags of these two units hanging side by side in the Army Medical Museum in Washington. Our battle death rates were higher than those of the Aviation, Cavalry, Engineers, Ordnance, or Quartermaster Corps. Those with a higher percentage than ours were the Infantry, the Tanks, the Artillery and the Signal Corps (the last but a fraction higher than the Medical Department).

These facts are eloquent. They show that while the Medical Department is what is sometimes called a "noncombatant service" (a misnomer for there is no such thing as a "noncombatant" in modern war), we, nevertheless, bear our proportionate share of danger. The missiles of the enemy do not discriminate, and the wearing of the red cross of the Geneva Convention is scant protection, as the foregoing data show. It must be remembered, too, that the soldiers with medical training go forward with the first elements of the advancing troops. And in withdrawals, some of which occurs in all wars, it is the medical unit that is the last to leave. Its duty in the place of danger is long.

MILITARY MEDICINE IS A SPECIALTY

Military medicine is a definite specialty, just as is ophthalmology or any other branch of medical science. It has its literature, its special practitioners,

and its ethics. It also has its handicaps, particularly one which does not affect any other medical specialty. This handicap is that in the past there has ever been a tendency for military medical officers to forget the lessons learned in the fierce light of warfare. Then, when once more war comes upon us—for there has always been a "next" war—it is necessary to learn military medicine anew, again in the hard way. The only practitioners of military medicine available have been the members of the small Medical Corps of the Regular Army and the medical officers of the National Guard and the Organized Reserves. These officers have been few, indeed, compared to the great number needed for war duty.

Fig. 2.—Bronze plaque in honor of Colonel Hoff. Placed within Hoff Hall, this tablet by the Gorham Company recalls a gallant medical officer's great contributions to training for field service.

DEVELOPMENT OF SCHOOLS OF THE ARMY MEDICAL DEPARTMENT

Nearly eighty years ago a wise Surgeon General, William Alexander Hammond (1828-1900), conceived the idea of forming an Army medical school in Washington, at which medical officers of our Army might receive preliminary instruction to fit them for their duties. He realized, as have all medicomilitary administrators, that the medical officer needs something in the way of training in addition to what he is taught at his medical school. Hammond went so far with his brain child as to select the professors, prepare the classrooms, and outline the curriculum. But his plans were disapproved by the Secretary of War. Mr. Stanton, who was his bitter personal enemy, finally had him tried

by court martial on a technical charge that resulted in his dismissal from the service. Years later Hammond was exonerated, but the Army Medical School had to await the advent of a more liberal Secretary of War.

Thirty years passed and the Surgeon General was the brilliant George Miller Sternberg (1838-1915), America's pioneer bacteriologist. Sternberg was more fortunate in the Secretary of War under whom he served, for Mr. Lamont approved of his plan to create the Army Medical School, so that in 1893 that institution came into being. It continues in its highly useful and protean work, filling a place that no other American institution occupies. The late Professor William Henry Welch (1850-1934) had a basis for calling it "America's oldest school of preventive medicine."

The Army Medical School has always given its students splendid training in certain techniques not ordinarily stressed, or considered only briefly, in the average medical school in the United States. Such work has included tropical medicine, helminthology, protozoology, advanced ophthalmology, and so forth. There used also to be found time to give a little practical instruction in drill, in equitation, and in field exercises. Such practical work was given in the grounds of the Walter Reed General Hospital or at Fort Myer. The Army Medical Center was not then contemplated, for the Army Medical School was miles away from the Walter Reed General Hospital, usually in rented quarters in downtown Washington. These arrangements were in effect until the end of the first World War.

In that great conflict medical officers once more learned military medicine, this time on a large scale. Contacts with medical officers of our allies, duty in far distant and hitherto unknown scenes, and highly specialized work, all had their broadening effect on American medical officers. When the war came to an end we had a highly efficient group of medicomilitary specialists in the Army. Then the huge army—at least it was huge by first World War standards—was demobilized. The Regular Army returned to its small size. The National Guard went back to the several States, and the Organized Reserves once more attempted to maintain a paper army and keep it trained with occasional periods of active duty in the summer, never more than a fortnight in extent. Had there been no other plan devised for keeping alive the lessons of military medicine bought at the cost of blood and human suffering, we would have been once more without any preparation when the second World War came upon us. But once more an able Surgeon General saw a way not only to keep alive what had been learned, but also to add to this sum of knowledge. That officer was Major-General Merritte Weber Ireland.

Surgeon General Ireland realized that thorough as was the training at the Army Medical School, that as essential as it is to the equipment of every medical officer of the United States Army, something more was needed. Fortunately for General Ireland's plan and fortunately for the Medical Department of the Army, there was already under the direction of the Surgeon General an ancient military post which was exactly what was needed. This was Carlisle Barracks, in the town of Carlisle, in the fertile Cumberland Valley of Pennsylvania, a hundred miles or so north of Washington. Carlisle Barracks was being used for General Hospital No. 31, devoted to reconstruction of disabled soldiers. It was

ideally located and all that was needed was for it to be turned over to the Surgeon General for permanent use as a training school for field duties of medical officers.

Accordingly, General Ireland addressed the following letter to the Secretary of War, through the Adjutant General of the Army:

"War Department
Office of the Surgeon General
Washington

April 28, 1920

"From: The Surgeon General.
"To: The Adjutant General.
"Subject: Medical Department Field School, Carlisle, Pa.

"1. I request that the U. S. Military Reservation at Carlisle, Pennsylvania, be permanently assigned to the Medical Department for use as a field school. Such a special service school is an urgent need in order that this department may comply with the policy announced in paragraphs 14, 15, 16, 29 and 30, G. O. 112, W. D., 1919.

"2. Facilities including construction exist at this post which may be converted to our needs in field training. Within two days by marching the prepared camp sites of the Gettysburg field are available. The use of adjacent mountain terrain for exercises has been offered to the Medical Department by a local townsman. The climate at Carlisle is such that alternation of season is found without undue extremes of heat and cold. The indoor season to be expected does not exceed three months.

"3. The need for the hospital at Carlisle will ultimately cease and the organization there will be listed for abandonment. If I understand correctly the use of this old post is not included in any General Staff plan for the future. I have considered, therefore, that the reservation could become available immediately and that there is no obstacle to its assignment to the Medical Department for field training purposes. Anticipating asking for a decision in this matter I have had made a preliminary survey of the site as to its suitability for this school. The results of this survey indicate that the selection will be an excellent one.

"4. It is my desire to have this school available about June 1 at which time a number of reserve officers and the present class of the Army Medical School would constitute the first class. In view of the urgency of this matter and the need of making arrangements for the abandonment of the hospital the earliest possible action is requested.

M. W. Ireland, Surgeon General, U. S. Army."

The Adjutant General of the Army, acting for the Secretary of War, indorsed the letter, under date of May 15, 1920:

"1. Upon the discontinuance of the United States General Hospital No. 31, the Medical Department is authorized to utilize for Medical Field School purposes the Carlisle Barracks Military Reservation, Penna., and the acreage adjacent thereto now occupied and controlled by the War Department by virture of permit from the Secretary of the Interior, dated August 22, 1918.

"2. The expenditure of funds by the Medical Department for the benefit of U. S. General Hospital No. 31, or the proposed Medical Field School, will be confined as closely as practicable to the territory contained within the boundaries of the Carlisle Barracks Military Reservation:

By order of the Secretary of War: G. H. Davis, Adjutant General."

Thus was born the Army's most important training center for medical officers in time of war. It has more than twenty-two years of efficient work to its credit and it has amply justified its inception. The post at which the Medical Field Service School was established is one of the oldest and most historic military reservations in our country. It merits a brief discussion of its history.

HISTORY OF CARLISLE BARRACKS

Carlisle Barracks was established in 1758 by the British Army, as shown by the "Military Papers" of Colonel John Stanwix, in the British Museum.

Stanwix was the first commanding officer of this post, established during the Seven Years' War, which was known in America as the French and Indian War. The British and Colonial troops occupied the present post during the long-continued hostilities with the Delaware Indians and other tribes. During the American Revolution, the Continental Army used Carlisle Barracks as a depot, and from there supplies and munitions were distributed. Hessian prisoners of war built the stone guardhouse at Carlisle Barracks; it is still standing and was until recently used for the purpose for which it was constructed. A School of Artillerists, probably the first school in the history of the United States Army, was established at Carlisle Barracks, 1778.

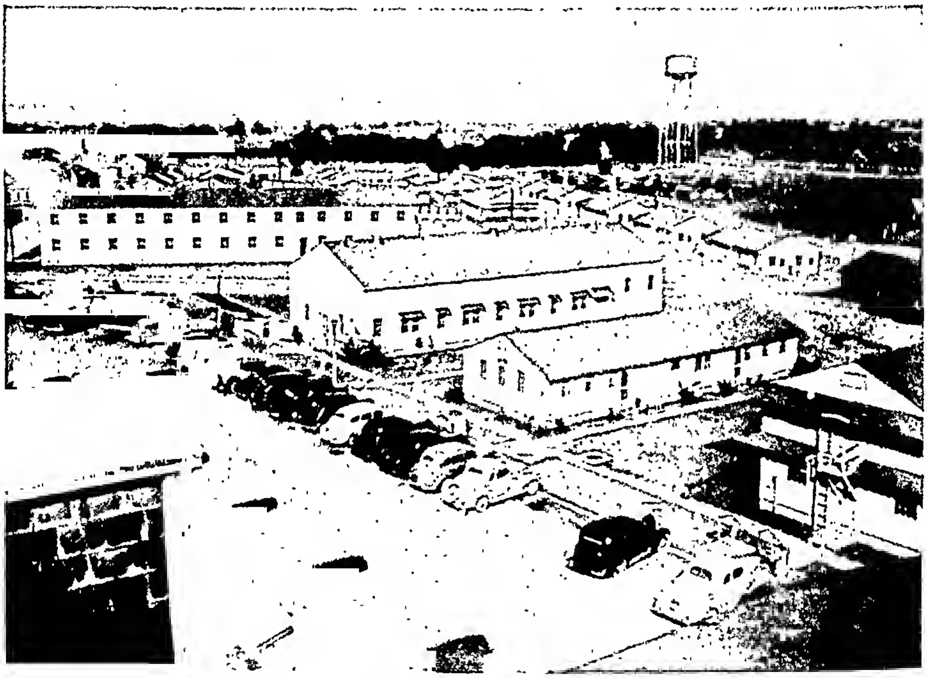

Fig. 3.—Temporary buildings at the Medical Field Service School. These are a few of the buildings for classrooms and barracks used for the accommodation of the large classes for officers and officer candidates at Carlisle Barracks, Pa.

American independence achieved, Carlisle Barracks was in the charge of the Ordnance Department of the Army, with the added function of being a recruit depot. During the Whisky Rebellion, in 1791 and 1792, President Washington sent an expedition, commanded by "Lighthorse" Harry Lee, father of General Robert E. Lee, against the four rebellious Pennsylvania counties. Carlisle Barracks was appointed the rendezvous for the Army. Some 10,000 to 15,000 troops were encamped on "the extensive common at Carlisle." President Washington came himself to Carlisle in the crisis of the rebellion, which was finally settled without bloodshed. At the time of the War of 1812 the old buildings used for the manufacture and storage of powder and shot during the Revolutionary War were reconditioned for the same purpose. When this second war with the mother country was at an end, a garrison, including both infantry and artillery, was continued at Carlisle Barracks.

In 1838 the War Department converted Carlisle Barracks into a recruit depot under the direction of an officer of dragoons. Here, in effect, was the Army's first cavalry school. At Carlisle Barracks, then, between 1838 and the outbreak of the Mexican War, were trained cavalrymen. From the post mounted units, both artillery and cavalry, departed for the southern theater of war. After that war the command at Carlisle Barracks devolved on Colonel Philip St. George Cooke, of the First Dragoons, a Virginian and General J. E. B. Stuart's father-in-law, who was destined to serve as a Union officer in the sixties. Shortly thereafter, a severe epidemic of cholera broke out, brought in, it was thought, by soldiers returning from Mexico. The post was quarantined, and the disease did not appear in the nearby town of Carlisle. Until the dark days of the War of 1861-1865 the post of Carlisle was typical of the United States Army station of the period, with the usual problems, vicissitudes, and development.

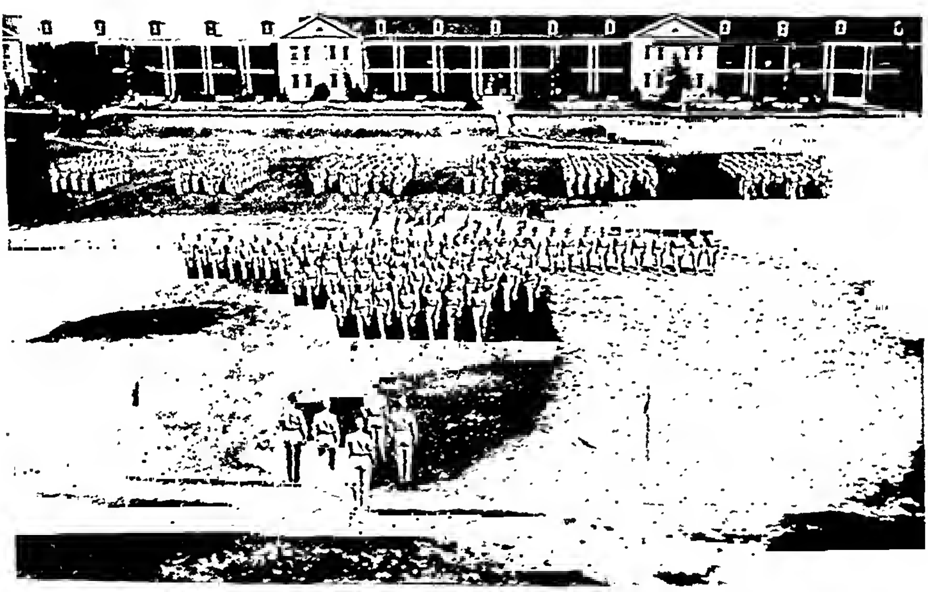

Fig. 4.—Parade of medical troops, Carlisle Barracks, Pa. Barracks of the 32nd Medical Battalion in background. (Photograph by James R. Gouffer of the *Evening Sentinel* of Carlisle.)

In the War Between the States, Carlisle Barracks became a supply center, as it had been during three previous wars. In 1861 it was the headquarters of the Mounted Recruiting Service of the United States Army. It not only saw the drilling of men recently taken into the service but also served as a place in which units withdrawn from the front were reconditioned, allowed to rest, and once more brought up to their strength. The fortunes of war were such that Carlisle Barracks was occupied by the Confederate troops, and General Fitzhugh Lee burned the buildings, with the exception, says a persistent tradition, of the quarters occupied by a West Point classmate. Thereafter, the post was rebuilt in part and surrounded by a wall within which drafted men were kept during their training. The war finally over, the post once more settled down to peacetime routine.

A part of the Sixth Cavalry was sent to Carlisle Barracks after the War. In 1867 it was suggested by the Surgeon General that selected enlisted men be trained as veterinary surgeons, and that the veterinary service not be placed under the Surgeon General, as the commanding officer of Carlisle Barracks had recommended. Thus a school for veterinarians was established at Carlisle Barracks. In 1871 the garrison of the post was ordered elsewhere, and for a time the post was closed, despite the pleas of the townsfolk of Carlisle. Matters dragged on until 1875, when Lieutenant Richard Henry Pratt (1840-1924), an officer deeply interested in the education of the Indian youth, established, under the authority of the War Department, the Carlisle Indian Industrial School. The Secretary of the Interior, Carl Schurz, gave it immediate support. Pratt, who ultimately rose to the rank of Brigadier-General, continued the direction of the Indian School until it closed in 1918. It made a splendid record during its nearly four decades of existence and achieved its objectives. The prowess of its students on the athletic field made it known to many who would not have been interested in the more serious side of its work.

In 1918 the War Department established General Hospital No. 31 at Carlisle Barracks, placing it under the command of Colonel (later Brigadier-General) Frank Royer Keefer, Medical Corps. The hospital did not actually begin to function until January, 1919, since much time was required for the conversion of the dilapidated buildings to hospital use. The institution became a reconstruction hospital wherein patients mutilated in the war not only were given adequate treatment but also were taught trades.

Before General Hospital No. 31 closed, Surgeon General Ireland requested the Secretary of War to assign Carlisle Barracks permanently to the Medical Department for use as a field school. This was done (see above) and the Medical Field Service School came into being on Sept. 1, 1920, the day that General Hospital No. 31 ceased to exist. The officer assigned as first Commandant was Colonel Percy Moreau Ashburn, Medical Corps. He was succeeded in 1923 by Major-General (then Lieutenant-Colonel) Charles Ransom Reynolds, who directed the school for eight years. His successors have been Brigadier-General Edward Lyman Munson (1931), Colonel Garfield Lesly McKinney (1932, acting), Brigadier-General Matthew Augustus DeLaney (1933), Brigadier-General Major Augustus Wroten Shockley (1935), Colonel Herbert Charles Gibner (1937), Brigadier-General Roger Brooke (1940), Brigadier-General John Mitchell Willis (1941, acting), and Brigadier-General Addison Dimmitt Davis, who has been Commandant since June, 1941.

THE FIRST FACULTY

The first faculty of the Medical Field Service School (1920) was composed of the following officers: Colonel Percy Moreau Ashburn, Commandant; Lieutenant-Colonel James Lung Bevans, Assistant Commandant; Captain Herbert Wellington Taylor, Secretary; Major Leon Connallin Garcia, Director of the Department of Administration; Captain Herbert Wellington Taylor, Director of the Department of Military Art; Major George Burgess Foster, Jr., Director of the Department of Field Sanitation; Major John Pierrepont Fletcher, Director

of the Department of Logistics and of the Medical Equipment Laboratory; Major Joseph Edward Bastion, Director of the Department of Enlisted Training and Commander of Demonstration Troops; and Captain Guy Blair Denit, in charge of Correspondence Courses. Many of these officers served at the Medical Field Service School for several years, and many of them have returned more than once for subsequent duty.

In 1923 Lieutenant-Colonel Charles Ransom Reynolds was appointed Commandant of the school, and to him is due its development and attainment of its important place in our scheme of military education. He served for eight years in this position of great responsibility, during which time he became known to nearly all medical officers of the National Guard and Reserves as well as those of the Regular Army. He became Surgeon General in 1935 and retired in 1939 to accept the directorship of the Bureau of Tuberculosis Control of the Commonwealth of Pennsylvania. Since General Reynold's administration of the Medical Field Service School no Commandant has served for as long as four years, due to the exigencies of the military service.

EXPANSION AND PROGRESS OF THE MEDICAL FIELD SERVICE SCHOOL

The Medical Field Service School, established as we have seen through the wisdom of the Surgeon General and the talents and hard work of its early faculty, did not spring fully developed into its present state. It was a gradual process, marked by many handicaps and delays. Instituted at the close of the first World War, it was given comparatively little financial support by the Congress of a war-weary nation. The most essential supplies were hard to get, and so short was the list of personnel that most of the officers had to occupy several positions simultaneously. It took good management, economy, and wise planning to keep it going. But those things it had, so that it passed through the hard times and was ready for the immense burden thrown upon it when the national emergency of 1940 arose. It was prepared for its present stupendous task of preparing the medical profession of the land for its part in the greatest war and the greatest danger that the United States has ever known.

Year after year the successive Surgeon Generals tried to obtain an appropriation for a new and adequate academic building at Carlisle Barracks. The school building first used was one of those built more than a half a century ago for the use of the Carlisle Indian Industrial School (1889). It was inadequate as to size, arrangement, and location. Finally, it was found to be actually unsafe, and the Secretary of War ordered it pulled down. Over the week end, for the matter was declared urgent, the old building was evacuated and the school was temporarily set up in the old gymnasium (1939). It was a matter of pride that not a day's instruction was lost in this wholesale change. But still no funds for a new building were forthcoming.

At length Congress in 1940 appropriated \$375,000 for a new academic building (Public 661, 76th Congress). Work on its construction began without delay and it was completed in 1941. The cornerstone was laid with appropriate ceremonies on June 26, 1941, by the Surgeon General, Major-General James Carre Magee. It was occupied by the Medical Field Service School on Oct. 6, 1941.

Thus when the emergency preliminary to the outbreak of the second World War was declared, the building was ready and has continued to serve as a nucleus of the school. With the enormous classes now being put through the school, it is, of course, inadequate in size, but with the temporary buildings constructed as classrooms there is sufficient space for the needs of the school.

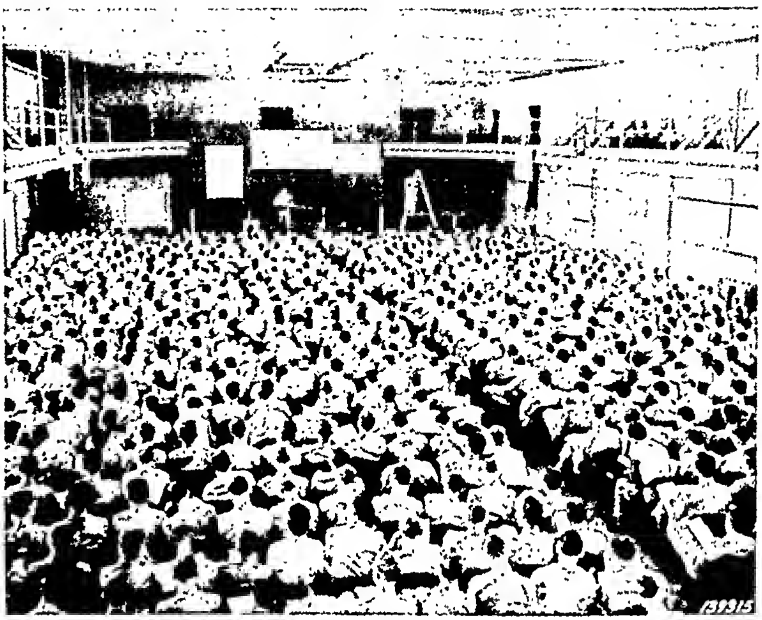

Fig. 5.—Officers class in medical tactics, Medical Field Service School, Carlisle Barracks, Pa. The school uses Tugo Hall, the gymnasium, for some of the large classes now under instruction. This building is named for Private Oscar C. Tugo of Boston, the first American soldier killed in the first World War. He was an enlisted man in the Medical Department. (Photograph by the U. S. Army Signal Corps.)

The academic building bears the name of the building that preceded it, Hoff Hall, named for Colonel John Van Rensselaer Hoff (1848-1920), pioneer proponent of adequate education in field duties for medical officers and enlisted men. On the cornerstone of Hoff Hall are carved words of a great British churchman, words that are as true now as when he wrote them nearly three centuries ago:

> "To Preserve a Man Alive in Midst
> of Chances and Hostilities is as
> Great a Miracle as to Create Him."
>
> *Jeremy Taylor.*

OBJECTS OF THE MEDICAL FIELD SERVICE SCHOOL

The objects of the Medical Field Service School are thus set forth in Army Regulations:

a. To instruct and train Medical Department officers of the Regular Army, National Guard, and of the Officers' Reserve Corps in the principles and methods of medical field service so as to increase their ability as instructors and to enhance their proficiency in the performance of their command and staff duties.

b. To instruct and train selected enlisted men of the Medical Department of the Regular Army, National Guard, and Organized Reserves in the duties of noncommissioned

officers pertaining to the organization, mobilization, training, and operation of Medical Department units of the components of the Army of the United States.

c. To act as an agency of the Surgeon General in the development and perfection of the principles and methods of medical field service.

d. To assist in the development of medical field sanitary equipment; to assist in the preparation and revision of Medical Department Training Regulations, instruction manuals, and other publications; to make research in matter pertaining to the field duties of the Medical Department; to disseminate to the service information pertaining to instruction and training used and developed at the Medical Field Service School.

It will be observed that these paragraphs from the "Army Bible" concern chiefly the Army as it exists in time of peace. Now that we are at war, the fundamental principles underlying the teaching at the Medical Field Service School have not changed, but the activities of the school have been largely directed in more specialized channels. There is no longer the division of the Army of the United States into the Regular Army, the National Guard, and the Organized Reserves, so that the instruction afforded at Carlisle Barracks is for all officers without distinction as to component of the large Army of the United States.

The teaching has naturally become much more elastic now than in days of peace. The curriculum has had to be radically changed several times, depending on the number of officers and others in each class, the period of time available for their instruction, the special duty to which the officer is destined by the War Department, the space available for teaching purposes and for quarters at Carlisle Barracks, and other factors. As information is received as to the medical service in our own Army and in those of other countries, the teaching at the Medical Field Service School is changed accordingly.

COURSES OF INSTRUCTION

As at all military schools, several courses of instruction are offered at the Medical Field Service School. Their nature and extent have been changed from time to time, depending on what military men call exigencies of the service. Prior to the declaration of the present emergency by the President, the following courses were being given at Carlisle Barracks:

Basic Course: This course was planned for junior or newly commissioned officers of the Medical Department of the Regular Army. It began early in January and normally was six months.

The National Guard and Reserve Officers' Course: Field officers (i.e., colonels, lieutenant-colonels, and majors) and senior captains of the Medical Department of the National Guard and the Officers' Reserve Corps attended for six weeks.

Advanced Course: Field officers of the Medical Department of the Regular Army, the National Guard, and the Officers' Reserve Corps received instruction for approximately three months.

Noncommissioned Officers' Course: This course, of approximately eight weeks' duration, beginning about September 15 each year, was provided for selected men of noncommissioned grades of the Regular Army, the National Guard, and the Organized Reserves.

Besides these formal courses at the Medical Field Service School, the three following types of summer camp were organized for instruction of officers and potential officers of the Medical Department of the Army:

Unit Training Camp for Reserve Officers: The officers receiving this instruction were, for the most part, assigned to medical units, though a few additional officers have been attached to the personnel of such a unit for the period of the camp. The units for which officers were so trained included medical regiments, medical squadrons, medical battalions, general hospitals, evacuation hospitals, surgical hospitals, and hospital centers. This camp has usually been of a fortnight's duration, beginning early in July of each year. Since the declaration of the existing limited emergency, this type of camp has not been conducted. Approximately 350 officers have been trained each year at this camp.

Basic Summer Training Camp for Reserve Officers: The instruction given in these annual camps, which also have been of two weeks' duration, has consisted mainly of basic military objects, including the employment of medical detachments and Medical Department units, Medical Department administration, mobilization, and sanitation. The chief objective of this camp has been to prepare the officers trained for more advanced instruction. Approximately 200 officers have enrolled in this camp annually.

Reserve Officers' Training Corps Camp: Here the course included instruction in the functions and activities of the Medical Department from the viewpoint of the enlisted man. The instruction included drill, function, and activities of medical detachments and of the medical battalion, squadron, and regiment, and general principles of sanitation, particularly in the field. The work at the R. O. T. C. camps supplemented that given by regular assigned instructors at various medical schools, and their instructors accompanied the students to the camp. The R. O. T. C. camps at Carlisle Barracks included 400 to 500 men each year and did not differ from similar medical R. O. T. C. camps elsewhere. At the camp held at Carlisle Barracks in 1941 the usual number of men were enrolled. The students successfully completing the full four years of Reserve Officers' Training Corps training were given reserve commissions in the Medical Corps of the United States Army.

Officers' Courses: The President's declaration of the existence of a limited emergency on Sept. 8, 1939, and of an unlimited emergency on May 27, 1941, changed the type of instruction offered at Carlisle Barracks, just as it did at other Army schools. There was no longer time to devote six months or more to a regular basic course; and the same was true of the other courses. A pressing need developed for training as large a number of officers of the Medical Department as could be and in as brief a time as possible. Therefore, a decision was made to establish courses of approximately one month each, known as *Refresher Courses.* The name was unfortunate, being borrowed from a type of course offered at some of the Army's other schools, designed for senior officers who needed a brief review. The new courses of Carlisle Barracks were attended largely by newly commissioned officers or those who had had little or no military experience, so that the courses were hardly "refreshers"; they were given to men who needed, and received, new information. This course is now known as the Officers' Course.

There were seven of these one month "Refresher" Courses given at the Medical Field Service School, beginning December, 1940. It was then decided that such brief courses did not permit sufficient training for the student officers, and so hardly justified their attendance. The period of training was, therefore, increased to two months, beginning with the course that opened on Sept. 2, 1941. Since then five two-month classes have been graduated, but the pressure of necessity then made it necessary to graduate five more of the one-month classes as well. Beginning in January, 1943, provisions for six-week courses will become effective.

Fig. 6.—Demonstration of work of medical soldiers in battle, Medical Field Service School. (Photograph by the U. S. Army Signal Corps.)

Officer Candidate Courses: Since the Medical Department of the Army has great need for officers to aid in its administration, but who need not hold medical, dental, or veterinary degrees, there was created the Medical Administrative Corps. Each Medical Administrative Corps officer releases a medical, dental, or veterinary officer for professional work, since the administrative functions would otherwise have to be performed by professionally trained officers. Any enlisted man of the Army who has had the minimum thirteen weeks' basic training may be recommended for admission to the Officer Candidate Class at the Medical Field Service School. Recommendations by the man's immediate commanding officer are based on his character, education, leadership, and other qualifications for commissioned rank. The Officer Candidate Course is three months in length. One group is admitted each month and one is graduated, so that a beginning, an intermediate, and a senior group are under training. A large proportion of the members of the Officer Candidate Classes are college graduates, and not a few hold professional degrees in law, engineering, or other nonmedical professions. Thirteen of these courses have been, or are being, held. This course in the future is to be given at the Medical Replacement Center at Camp Barkeley, Texas, will be related below.

Cadre Course: This course of one month's duration is designed to train medical officers being assigned to newly created divisions of the Army. Thought is given to the special needs of such officers, part of whose instruction is therefore different from that of the members of the regular officers' classes.

Medical Inspectors' Course: A one-month course for selected officers in field sanitation and preventive medicine. It is specially designed, as its name indicates, for officers who are to serve as medical inspectors, who correspond in duty somewhat to civil health officers.

DEPARTMENT OF THE MEDICAL FIELD SERVICE SCHOOL

The work of the Medical Field Service School is different from that of any other type of school that its students have known. It is so little understood by the public, that a consideration of the several departments is desirable. It will be observed that the school does not concern itself with the teaching of clinical medicine or with laboratory procedure. Such subjects are more properly taught at the Army Medical School and at its sister institution, the Walter Reed General Hospital, both at the Army Medical Center in Washington. The work of the Medical Field Service School and that of the Army Medical School is so arranged and coordinated by the Division of Training of the Surgeon General's Office that there is no conflict. There is likewise no conflict with the work of the School of Aviation Medicine at Randolph Field near San Antonio, Texas.

The officers in charge of the several departments of the Medical Field Service School have cooperated with me in preparing the following detailed statements, which have likewise been checked by the Assistant Commandant. The Assistant Commandant is in direct charge of the instruction given at the Medical Field Service School. His function is similar to that of a dean of a college or university.

Department of Military Art.—The mission of this department is the instruction of Medical Department personnel in the principles of medical support of combat operations. To this end, there are taught the basic principles of warfare, the military policy of the United States, the organization, tactics, and combat dispositions of the basic arm of the service, the Infantry, and the supporting arms and services, the Artillery, Cavalry, Armored Force, Air Corps, Engineers, etc. Correlation and mutual support of these arms and services in coordinated action are taught.

With combat tactics as a background, students are taught the principles of medical support of attack, defense, and special operations, such as river crossings, landing operations, retrograde movements, and pursuit. Early in the instruction students are taught the use of military symbols, map reading, and practical application of maps to terrain. Military maps include general, strategical, tactical, topographical, and photographic maps. Some of the exercises require close attention to orientation both in daylight and in darkness. Teaching methods include conferences, daily application terrain exercises, demonstrations, training films, map exercises, and examination.

Instruction is given in the preparation of medical and unit plans, preparation and use of standing operative procedure, and the formulation and issuance of combat orders to put plans into action. In addition to medical support of combat, instruction includes medical support of troops in bivouac and on the march.

The scope of the instruction in military art is such as to train medical officers in the principles of combat and the medical support thereof to such a degree that such officers can function efficiently under all conditions.

Department of Military Sanitation.—The old adage about the relative value of the ounce of prevention and the pound of cure is nowhere more true than in the military service. The Medical Department has the duty of treating sick and wounded soldiers. But it also has the far more important responsibility of keeping men well. To this end, all the teachings of preventive medicine and sanitation are used in the development of procedures designed for the maintenance of the soldier's health. In the field, in particular, modern sanitation is of the utmost importance. The course offered at the Medical Field Service School is designed to instruct students in the established practical measures for the preservation of the health of our fighting men. Thus, the prevention of disease is studied, not only as understood in our own climate, but in

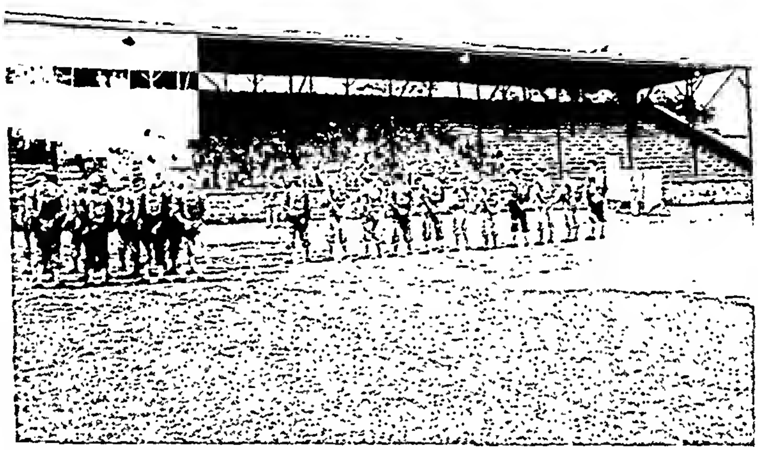

Fig. 7.—Demonstration of the work of a medical battalion. The instructor (at right) uses charts and diagrams. The medical soldiers actually demonstrate the principles taught. This exercise is on Stark Field, the only spot in America where troops have been drilled for every American War. (Photograph by the U. S. Army Signal Corps.)

the various other climates in which our forces may be sent by the exigencies of modern war in all its world theaters. Stress is placed on control measures against communicable diseases of military importance, including venereal diseases. Students are taught how to construct and maintain field devices and apparatus for the purification and safeguarding of water supplies, for the disposal of body and other waste, for the preservation, transportation, and preparation of food, etc.

The "Sanitary Area" consists of full-size models of various devices used by troops in the field, such as incinerators, water sterilizers, and the like. The control of insect and other vectors of disease is an important part of the curriculum. For instance, officers and officer candidates are taught how to protect the soldier from flies, lice, fleas, mites, ticks, ants, bedbugs, mosquitoes, midges, roaches, leeches, rodents, and a host of other pests and vermin. Of particular

importance is special consideration of jungle sanitation, the sanitation of commands in desert country, and in the cold climates of the far north. Protection against snakes and other venomous animals is studied. The proper methods of conducting sanitary inspections are taught.

At first thought one may suppose that military sanitation is no different from sanitation in civil communities, *mutatis mutandis*. But this is not true. In the Army the military situation must ever be supreme. The health of the men is to be maintained though the medical or health officer may have no voice in the determination of the nature of that situation. A civil health officer may place a placard on a house wherein there is a case of a communicable disease. Thereafter to enter such a house is to violate the law, and punishment can be brought about by the health officer. The military health officer, on the other hand, cannot say merely that certain area or place is dangerous because it contains communicable disease. He cannot order soldiers, in other words, to keep out of a dangerous area. He may well know that a certain place contains malarial mosquitoes, but if the military situation demands that the commander take his troops through that area, through it they must go. A military health officer must, therefore, be prepared to tell his general how best to prevent the occurrence of malaria, even though he knows that the men must be exposed. Our Department of Military Sanitation has not only to review the general principles and practices of sanitation, but also must teach its students how to make the best of situations actually to be faced. Actuality, and not theory, must govern.

Department of Administration.—Bookkeeping and the maintenance of records are boring to the average person. "Paper work," as it is termed by military men is, however, recognized as a necessity. No business firm or other establishment can run without records of what it is doing, and without the proper keeping of accounts and returns. Administration in the military service has been greatly simplified, but a minimum remains and always will remain.

The instruction of the Department of Administration, therefore, includes all the military activities of the Medical Department save the tactical and technical employment of units or personnel. This broad classification includes the methods of the procurement of supplies and the accounting for them. Supplies may be those acquired by the Medical Department (which like the Engineer, Signal Corps, Ordnance, and Quartermaster Departments, is a "supply department") or those used by the Army in general. Thus, students are taught how to make out the required reports, requisitions, returns, and other administrative procedures necessary in the proper care and disposition of sick and wounded soldiers. This includes the administrative procedures incidental to the procurement and maintenance of shelter and food for patients and medical personnel necessary to care for them. Military law is taught by this department, for all officers must understand court martial procedure, since such duty is occasionally unavoidable. The proper relations between military and civil power must be made clear. The organization and operation of the important military units of the Medical Department are taught, such as the various types of military hospitals.

In the instruction by this department, accuracy and rapidity of accomplishment of administrative duties are stressed. A considerable part of the time allotted to the Department of Administration consists of applicatory exercises in which the student is presented with actual or simulated administrative situations of the types likely to be encountered in actual service. These problems he is required to solve in accordance with prescribed Army administrative procedures.

Those who may think that it is a waste of time, in these days when time is so precious, for officers and officer candidates to have to learn administrative procedures, must remember the ultimate importance of adequate medicomilitary records. It is the Medical Department which must be prepared to tell the commander of troops just how many men he actually commands. It means little for a general to command a division, for instance, which has a strength of ten thousand men "on paper," if he does not know how many of his supposed strength are fit to fight. If 10 per cent of his command be sick or otherwise noneffective, then he commands not ten thousand men, but only nine thousand. He has only one source for the information that is vital to him and to the military success of his force. That source is the Medical Department. The senior medical officer can tell him—but only if proper records are kept by all medical personnel.

In our country we have always been generous in the matter of pensions, bonuses, compensations, and the like for former soldiers. In the old days when medical records were incomplete or wanting, many men could not prove their right to Governmental financial aid. Some worthy men, therefore, were not given the money to which they were entitled by law. In other instances, men were able to obtain money to which they were not entitled, because of incomplete records. Thus, the Medical Department of our Army has a double duty in the matter of keeping correct and adequate records. It must protect the rights of the future veteran, and it must protect the taxpayer. Records, then, are of very great importance.

Department of Training.—The training of soldiers is one of the prime functions of officers in any branch of the Army. Soldiers are made not born. No man springs fully armed from the brow of the Goddess of Wisdom nor from the brow of the God of War. Yet he must have some of the knowledge of Minerva, the skill of Mars, together with the cunning of Aesculapius, if he is to be a good medical soldier. The Department of Training devotes its energies chiefly to teaching officers and officer candidates how to train the men in the ranks. Its courses are designed to familiarize students with the basic principles of military instruction and the manner in which such subjects may be imparted to enlisted men of the Medical Department. The curriculum includes lectures, conferences, and demonstrations, all used to orient the student as to the general and special conduct of military instruction in its several phases. For purpose of physical training and body coordination, a systematic series of drill and calisthenic periods are conducted.

The work in military training is designed to familiarize the student with the methods of instruction useful in, and appropriate to, the military service. The mechanism of teaching is shown, with consideration of such factors as the

emotional and psychological approach, as required in training the medical soldier for combat duty. Particular emphasis is placed on the use of the visual sense for instructional purposes, and following this, by the applicatory method.

Military courtesy is taught both for itself and as an aid to achievement of military discipline. Instruction is given in both indoor and outdoor courtesies. Stress is placed on the relations necessary between officers and enlisted men, between officers, honors, and courtesies rendered to the flag, the National Anthem, commanding officers, and at ceremonies.

The inspection is a necessary feature of army life, since standards to be reached and maintained must at all times be closely scrutinized by officers concerned. The proper mode of conducting inspections is taught, including inspection of barracks and tents, unit inspections, and inspections of the soldiers' equipment. The class itself is periodically inspected by the commanding officer, which serves a direct purpose and likewise an indirect one, since it teaches how such duty should be performed.

In the preparation of training programs and schedules, the students are taught how to make the most of the time available for training their men, ever with an eye to the need for the particular unit being trained. From the estimate or analysis (the British say "appreciation") of the situation, a program for training is developed, out of which, in turn, a systematic schedule is produced. A part of the class instruction consists of an illustrative problem which takes them through the several procedures mentioned. Emphasis is placed on progressive step-by-step training, continuity of subject matter, variation in methods of instruction and approach, and decentralization of effort in teaching. Such schedules are worked out in detail in the classroom, and discussion is encouraged.

Instruction is given also in the movements of dismounted drill by demonstration and group instruction, followed by student application of each movement. To overcome awkwardness and diffidence, the class conducts cadence drill in which members collectively give the commands to the unit. This is followed by a period of command exercises in which each officer individually is called upon to drill the unit. Emphasis is placed on the disciplinary effect of drill, its possibilities in teaching precision and teamwork, and the instillation of prompt response.

By means of conferences, demonstrations, and application, the classes are instructed in litter drill, ambulance loading, physical training, use of the Army leg splint, and the assembly and adjustment of the medical soldier's field equipment.

Department of Logistics.—Logistics is defined as "that branch of military science which takes cognizance of the comparative warlike resources and capabilities of countries between which war is likely to arise, as well as of all conditions it is likely to be conducted, such as the geographical features, climate, means of transit, food resources, etc., of a probable seat of war." The more narrow application of the term logistics implies the study of the movement of troops and supplies, with reference to the factors which affect such movements.

At the Medical Field Service School the student is taught how to operate, maintain, and employ the motor transportation assigned to medical detachments, battalions, squadrons, and regiments. The teaching also includes study in-

Fig. 8.—Demonstrations of the use of the wheeled litter. (Photograph by the U. S. Army Signal Corps.)

Fig. 9.—An operating table made by placing ends of the litter on two medical chests at the Aid Station. (Photograph by the U. S. Army Signal Corps.)

volving the intricate problems of supply of medical units, and the problems incident to the medical supply of all units in the field.

The matter of transporting medical personnel and medical material from one place to another is far from being as simple as it may appear at first thought. Without a knowledge of the broad problem, one might think that when one wishes to move medical units from point A to point B, one has merely to look on the map and find the nearest road connecting the two points and order the medical units to proceed over that road. But perhaps that obvious road may be under the enemy's fire; or perhaps it is being used by our own advancing infantry; or perhaps we have just learned that the bridges over which that road passes have been destroyed. Thus one must be prepared to find other roads or to move across country in some instances. It all involves not only a knowledge of the terrain, but up-to-the-minute knowledge of the military situation, where our own troops and those of the enemy are disposed, and full information as to the condition of our vehicles and of the roads. And many other factors besides. Logistics is not a simple subject.

Department of Field Medicine and Surgery.—A relatively new addition to the Medical Field Service School, having been created in June, 1941, is the Department of Field Medicine and Surgery. The department collects and evaluates current information as to medical service in the field, particularly during combat. This information is communicated to the students and other personnel of the school. New drugs, new types of treatment, and new apparatus are studied. Matters pertaining to the prevention and treatment of trauma and disease in forward battle areas—the divisional area in general—are included.

This department teaches officers of the Medical Department how to make the best use of the material available at a certain place and under certain conditions. The Medical Department rarely, if ever, has the choice as to such conditions. Officers must learn to carry on with what they have; they should not be helpless if they are not provided with every convenience to which they may have become accustomed in civil practice. In these days of modern hospitals with fully-equipped clinical aids, some of the resourcefulness and ingenuity of the older generation of practitioners has been lost. Such qualities are essential in the military service. On the field of battle the medical officer must be prepared to treat wounded men with the best emergency measures available. Treat them he must, whether or not his supplies have arrived, or whether or not they have been exhausted.

This department considers such matters as first aid at the site where the injury has been sustained; emergency medical and surgical treatment in the battalion, collecting and clearing stations; principles and practices in the use of plasma, human albumin, and human blood, wherever applicable; prevention and treatment of shock, hemorrhage, and infection; principles and practice of the triage or sorting of the wounded; chemotherapy in its application to field medicine; medical care of gas casualties; use of anesthetics in the field; use of personal protective equipment and devices in relation to the prevention of injury and disease; the physiology of wound healing and the emergency management of wounds; consideration of medical and surgical equipment, including sutures, ligatures, dressings, splints, medicaments, etc. The department sums up its

duties in the words: "The application of the best medical and surgical care of the greatest number of sick and injured soldiers at the front, with a minimum of trained personnel and material."

Department of Dental Field Service.—The prime duty of this department is the instruction of officers of the Dental Corps in the organization and functions of the Medical Department units, in order that such officers may accomplish their professional and administrative duties most effectively in both fixed instillations and tactical commands. The course emphasizes the cooperation of medical and dental officers, and prepares the latter to serve as auxiliary medical officers when circumstances require.

The officers' classes at the Medical Field Service School include officers of each of the several corps of the Medical Department. Much of the instruction is given to the entire class. However, there are certain administrative functions of medical officers, for example, which do not apply to the Dental Corps, and vice versa. While the medical officers are being given such instruction, the dental officers are given, in separate classes, the work which applies to them alone. This arrangement has been found most satisfactory to all concerned.

Some of the special instruction afforded dental officers includes: duties of dental officers of all units, *Army Regulations* of particular interest to the Dental Corps, dental examinations and surveys, training of dental assistants, dental field equipment and treatment of jaw fractures in the field (with approved methods of splinting). The instruction in these various subjects is by conferences, applicatory exercises, and demonstrations.

Department of Veterinary Field Service.—This department furnishes, particularly to officers of the Veterinary Corps, essential information concerning the prevention of transmission to military personnel of the communicable diseases of animals. Thus special study is made of the protection of human beings from unsound food of animal origin (milk, meat, butter, eggs, cheese, etc.). Veterinary officers are given special instruction in medical field service, special emphasis being placed on the hospitalization and care of animals.

The special training afforded dental officers in their particular duties during periods when medical officers are receiving training not applicable to the Dental Corps, holds true also of the veterinary officers. While the medical and dental officers are each receiving special instruction not of interest to the other group, the veterinary officers are under the instruction of officers of the Department of Veterinary Field Service for special training necessary for their duties.

Among the special subjects taught by this department are: the preparation and rendition of the field veterinary reports and returns, together with other administrative work concerning animals; and the supply and inspection of food products. Other topics are the preservation of animal health, methods of preserving and storing foods of animal origin, veterinary aspects of chemical warfare, technical and tactical employment of veterinary units. Special attention is paid to the veterinary facilities with various arms and services. This last includes the care and treatment of animals under field conditions.

General Instruction.—Besides the teaching in the departments just outlined, special instruction is afforded in a number of special fields not directly connected with any department. There are lectures and conferences on such

topics as public speaking, consideration of medicomilitary problems of the past and present, notes on the medical services of the United States Navy, the United States Public Health Service, the Veterans' Administration, and that of various foreign armies.

Gettysburg is only about 28 miles from Carlisle Barracks, so that the classes, when time permits, are taken there for a tactical visit to the battlefield. There an officer explains the battle in detail, including the medical problems that arose. The battlefield of Gettysburg is used for map problems by every school in the United States Army, but only the Medical Field Service School is near enough to have teaching take place on the terrain itself.

Extension Courses.—The department of extension courses has the duty of preparing instructional material for use in the training of officers and enlisted men, particularly those of the Medical Department. The material prepared includes a lengthy series of Field Manuals, Technical Manuals, Training Films, Film Strips, and the Army Extension Courses. These training aids and texts include material on many phases of medicomilitary training. The data prepared by this department are distributed to the various posts and stations of the Army, and are utilized by officers and men in their training for war duties.

The series of correspondence courses formerly offered by this department is not being used under war conditions, since more extensive training is now permitted, and few persons not on active military duty would be interested in pursuing such courses.

Liaison Officers.—A modern army is a complicated machine. In order to understand the proper function of any of its parts, it is essential that the general working of other parts be thoroughly understood. It is like working a jigsaw puzzle. One must know the shape of the pieces already on the board before he can fit the piece in hand into the complicated mosaic of the whole.

To achieve this, the Medical Field Service School has several officers of other branches of the United States Army on its faculty. They teach the students the work of their particular branches and give information to other departments of the school on the technical and tactical side of their work. This system has been found most effective. There are medical officers, graduates of the Medical Field Service School, on duty at most of the other service schools of our Army. At the Medical Field Service School there are at present on duty as liaison officers, senior officers of Infantry, of the Armored Force, and of the Chemical Warfare Service. We are also highly fortunate in having a Colonel of the Royal Army Medical Corps of Great Britain, an officer of wide experience and training, who not only gives the greatest assistance in the teaching and the preparation of programs and plans, but also frequently visits medical installations in the field in many parts of the United States. He has been of great value in the work of the School. An officer from the Medical Field Service School has visited the Royal Canadian Army Medical Corps Training Centre at Camp Borden, Ontario, to study the work of that school and to give lectures on the work of the American school. Similarly, officers from the Canadian school have made visits to Carlisle Barracks for similar purpose. Such exchanges of visits will be continued.

Fig. 11.—Work of a Battalion Aid Station. Demonstration at Carlisle Barracks. (Photograph by the U. S. Army Signal Corps)

Contact with other branches of the Army and with the Medical Corps of the Navy and of the United States Public Health Service is readily maintained by means of visits of personnel to Washington, which is only a hundred miles distant.

PUBLICATIONS

The Medical Field Service School publishes three important scientific periodicals. They are all quarterly publications and they are all edited in the Surgeon General's Office, War Department. They are *The Army Medical Bulletin* (established 1921 and now in its sixty-fourth issue), *The Dental Bulletin* (now in its thirteenth volume), and *The Veterinary Bulletin* (now in its sixteenth volume). From time to time special texts are published. Such books are primarily for use in the instruction of the various classes at the Medical Field Service School. Other texts of wider application are used throughout the Army, and are often adopted as texts by schools and colleges not connected with the miltary service. Most recent of the latter class of books is *Elements of Military Hygiene*, the second edition of which is just off the press. It was written primarily for Cadets at the United States Military Academy, but it will doubtless have other general use.

Some of the material is issued in mimeographed form, but the greater part is printed. The Print Shop of the Medical Field Service School is now working twenty-four hours a day and is turning out an immense volume of material. The *Army Medical Bulletin* has a circulation of nearly 20,000; the *Dental* and *Veterinary Bulletins* have somewhat less.

The Book Shop of the Medical Field Service School sells the publications for practically cost to persons not students. Students are issued all necessary texts without cost.

The Art Department of the School prepares military maps, sketches, charts, diagrams, overlays, and the like, for use in connection with instruction. Such material is often issued in large quantity.

NUMBER OF GRADUATES OF THE MEDICAL FIELD SERVICE SCHOOL*

COURSE	DATE COURSE FIRST GIVEN	NUMBER OF GRADUATES
Basic Course	1920	1,369
Advanced Course	1921	217
Field Officers' Course	1923	273
Officers' Course (formerly Refresher Course)	1940	6,838
Special Cadre Class	1942	376
Noncommissioned Officers' Course	1924	1,129
Sanitary Specialists' Course	1940	712
Officer Candidate Class	1941	2,132
Medical Inspectors' Course		51
	Total	13,097

SUMMER TRAINING CAMP	DATE CAMP FIRST HELD	NO. MEN COMPLETING TRAINING
Basic Training (June)	1925	1,620
Regimental Training (July)	1923	4,655
Hospital Commandus	1928 (discontinued in 1931)	188
Reserve Officers' Training Corps		6,198
	Total	12,661
	Grand Total	25,758

*As of December 1, 1942.

DEMONSTRATION TROOPS

It is obviously impossible to give practical instruction in medical field service without demonstration troops. Our wise Chinese friends tell us that one picture is worth a thousand words. It is certainly true in teaching military science and art. When the Medical Field Service School desires to show how military medical units are set up and how they function in the field, practical demonstrations are arranged. Actual aid stations, collecting stations, clearing stations, field hospitals, and the like, are set up before the eyes of the students. Students help in such demonstrations and the picture is indelibly impressed on their memories.

At Carlisle Barracks there are a series of what the soldiers call "wars"; that is, demonstrations of the work of the Medical Department in selected typical military situations. A simulated "front line" is fixed, and men taking the part of wounded are evacuated therefrom through the various stages, through the various echelons, to the rear where they are to receive treatment in the appropriate hospital. Of course, in such demonstrations the distances between units and stations is foreshortened. Otherwise the stage is set as nearly as possible like the real thing.

The First Medical Regiment, a part of the First Division, was long stationed at Carlisle Barracks and served as demonstration troops. When the reorganization of the army took place in 1940, and the large or "square"* division of the first World War was abandoned, it was necessary to change the demonstration troops at Carlisle Barracks. The First Medical Regiment was transferred to Fort Ord, California, since for a time the National Guard retained the "square" divisions. In its place at Carlisle Barracks there was created a new medical organization, the Thirty-Second Medical Battalion, some of the seasoned men of the First Medical Regiment being retained as a nucleus of the new body. The new or "triangular"* division of our present Army is much smaller than the old "square" division, and has a medical battalion instead of a medical regiment. Our new demonstration organization has taken over the splendid barracks constructed for the medical regiment and the work goes on.

The mission of the Thirty-Second Medical Battalion is thus to demonstrate to students of the Medical Field Service School the current methods of performing those military functions which are outlined in theory from the lecture and conference platform. It shows how the provisions of *Army Regulations* and the numerous *Training Manuals* should be carried out. Thus, its work differs somewhat from that of any other medical battalion, for it merely shows how to give medical support to an infantry division, but does not have actual care of patients. It could at any time take the field and perform such duties.

The Thirty-Second Medical Battalion has to be able to demonstrate the work of any medical battalion, and something more. It must also be prepared to demonstrate the work of other medical units, such as those which normally function in the front and in the rear of the medical battalion in combat. In

*The "square" division was so called because it consisted of two brigades, each including two infantry regiments with supporting artillery and service troops. A "triangular" division consists of three infantry regiments with supporting artillery and service troops. The "square" division included some 22,000 men and was in vogue in World War I. The "triangular" division of some 15,500 men is the only infantry division now found in the United States Army.

other words, its personnel must understand not only their own work, but also the work of many other instillations. To insure better discipline its men use rifles in drills, it being understood that in actual field operations rifles would not be used. Medical soldiers are unarmed, except for a small number of automatic pistols, authorized by the Geneva Convention for self-defense and for the defense of patients in their care.

Since the demonstration troops at Carlisle must be able to stage mimic battles, the men of this organization must be able to play the roles of infantry, artillery, and other troops for demonstration purposes. They are like a stage army, but a stage army that can actually do in real life the things they demonstrate on an outdoor "stage" covering many square miles. The officers, many of whom are graduates of the Command and General Staff School at Fort Leavenworth, must understand the tactics and technique of the other arms and services.

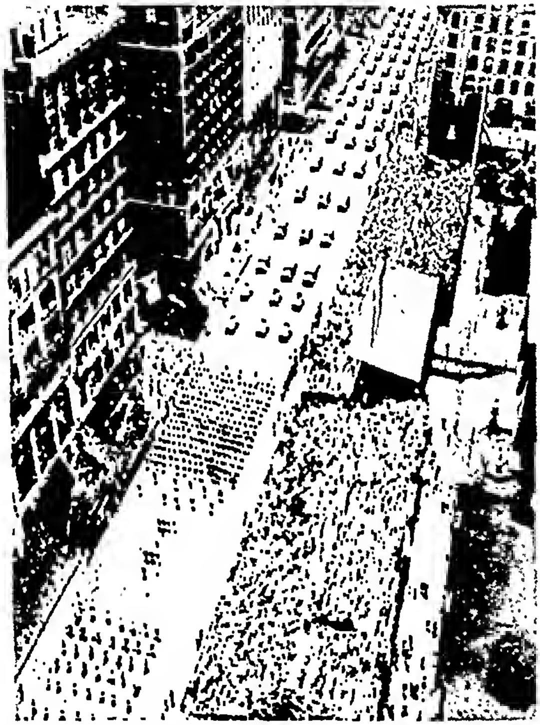

Fig. 12.—Carlisle Barracks Troops at the New York Flag Day Parade, June 14, 1942. This photograph by A. F. Sozio was taken without the knowledge of the 32nd Medical Battalion and the Medical Field Service School Band here seen passing the reviewing stand. The fine military appearance of these soldiers won them the official commendation of Lieutenant-General Hugh A. Drum, Commanding the Second Army.

The skill acquired by the personnel of the demonstration troops at Carlisle Barracks has resulted in frequent withdrawals of cadres of officers and men to form the nuclei of new organizations. They are the leaven which causes a new medicomilitary unit to develop to its desired size and skill.

EQUIPMENT LABORATORY

The Medical Department Equipment Laboratory is one of the important entities of Carlisle Barracks. Here are developed apparatus and appliances for use by the Medical Department in the field. New ambulances and other

vehicles are built and tested. New articles of equipment, such as first-aid packages and containers, field x-ray apparatus, litters, and equipment for battalion aid stations, are developed. Indeed, whenever a new problem as to medical supplies or equipment arises, it is this laboratory on which falls the duty of creating a model to fill the need. Many of the now standard articles of medical equipment were first only working models at the Medical Department Equipment Laboratory, and after passing rigid tests, were finally adopted by the War Department on the recommendation of the Surgeon General.

The variety of equipment and apparatus developed at the Medical Department Equipment Laboratory is very great. Some of the articles long in standard use in the military service had their origin in working models developed in this laboratory. Some of the more recent models include:

1. *Four-Wheel Drive Cross Country Ambulance:* With a capacity for four litter or seven sitting patients, this ambulance can operate over roads in any condition or cross country.

2. *Multiple Motor Ambulance (Bus Type)*: This vehicle operates at rapid speed over paved highways and at moderate speeds over rough roads. It has a capacity for 20 sitting patients or 12 litter patients.

3. *Animal-Drawn Cavalry Ambulance:* Even in this age of mechanization our Army still has some horse cavalry and horse-drawn artillery. Obviously, to be of service to such units, ambulances must be able to go wherever the units themselves go. This ambulance answers such requirements. Its low center of gravity makes it hard to overturn and makes it most effective on rough terrain.

4. *Mobile Surgical Hospital:* This unit is actually a hospital, contained in fourteen vehicles. There are seven large vans, of the semitrailer or bus type, four of which are complete operating rooms, the fifth a sterilization room, the sixth an x-ray room, and a supply room and office. There are also two power trucks for supplying electric current, two cargo trucks, one of which is a kitchen; one Engineer Purification Unit truck, and two command cars.

5. *Mobile Army Medical Laboratory:* One large motor van is thoroughly equipped for laboratory work in the field.

6. *Hospital Trains:* This includes a twenty-ton box car, for use in the combat area. The hospital train includes 16 ward cars, two cars for Medical Department enlisted men, one car for officers and noncommissioned officers, one dressing and dispensary car which includes the kitchen, and one utility car. Besides these the number of ward cars varies according to the immediate needs, depending on the number of casualties. A hospital train unit car, built by the Pullman Company in accordance with the specifications of the Medical Department Equipment Laboratory, was sent to Carlisle Barracks for study. It is designed to furnish food and operating room facilities for a full trainload of patients in the Zone of the Interior. Attached would be a baggage car and a variable number of sleeping or chair cars.

7. *Arctic Medical Unit:* Full equipment is carried in a pack by the medical soldier on skis. In transporting the wounded the skis and litter form a sled for the patient while the medical soldier uses snow shoes.

Among the other pieces of equipment more recently developed are a portable field disinfector, wheeled litter carrier, pack carriers for equipment of medical detachments, folding arm splint, folding leg splint, flight service chest for use by medical units with the Air Forces, field operating light with generator, new individual equipment for the medical soldier and for the medical officer, a new first-aid packet, a portable still, chemical heat pads, neon emergency operating lights, and new medical equipment for parachute infantry. A recent development is the medical equipment for use with parachute troops, material that can withstand parachute dropping.

The foregoing articles of equipment were displayed by the officer in charge of the Medical Department Equipment Laboratory and his staff at the meeting of the American Medical Association in Atlantic City, June 6-12, 1942. The greatest interest was manifested by delegates and other visitors.

Medical Field Service School's First War Casualty.—On March 26, 1942, Major James Augustus McCloskey (1909-1942), Medical Corps, a graduate of the Medical Field Service School in 1937, was killed in action in the Bataan Peninsula, Philippine Islands. He is our first war casualty, though there have been others reported since. A tablet in his memory has been placed in the Chapel of the Medical Field Service School, dedicated with appropriate ceremonies.

Medical Administrative Officer Candidate School at Camp Barkley, Texas.—So great has been the need for officers for the Medical Administrative Corps that on April 15, 1942, the War Department ordered the creation of a second school for the training of approved candidates. It was established at Camp Barkeley, Texas, and was organized so rapidly that the first class began its instruction on May 9, 1942, and has since been graduated. This school is doing work comparable with that carried on at Carlisle Barracks, though, of course, with less equipment. No instruction of officers is given at Camp Barkeley.

While the Officer Candidate School at Camp Barkeley is not a branch of the Medical Field Service School, it is, in effect, an offspring of it. The Commanding General of the Medical Replacement Center at Camp Barkeley, Brigadier-General Roy Cleveland Heflebower, is a medical officer, and the Assistant Commandant and other members of the faculty of the Camp Barkeley School were taken from the faculty of the Medical Field Service School. The curriculum at Camp Barkeley is essentially the same as that of Carlisle Barracks. The medical soldiers at Camp Barkeley furnish ample demonstration units in connection with the training of the officer candidates.

Since the preparation of this report, the War Department has ordered that effective January 1, 1943, the Officer Candidate Classes at the Medical Field Service School be discontinued upon graduation. Thus by March 1, 1943, there will be no more student candidates under instruction. In future the training of candidates for commissions in the Medical Administrative Corps will be carried out at the Medical Replacement Center at Camp Barkeley, Texas. Thus the whole effort of the Medical Field Service School will be devoted to the training of officers. The course will be extended to six weeks instead of one month as at present. The special courses for officers will also be given at Carlisle Barracks as needed.

CONCLUSION

The medical profession of our country owes much to the Army Medical Department. Some of the greatest advances of American science have been made by our medical officers. Many of them are not well known as Army gifts. Army medical officers have *inter alia* given our country its first medical book, its first pharmacopoeia, its first textbook on bacteriology, its greatest bibliographical work—the Index Catalogue of the Army Medical Library. Army medical officers introduced vaccination to America, developed our present system of typhoid fever prophylaxis, showed that the mosquito transmits yellow fever, created America's first school of preventive medicine, developed the largest medical library the world has ever known, established the largest medical museum in America, first showed the importance of proper ventilation, created the first large American hospital (the New York Hospital), introduced photomicrography, invented the purification of drinking water by liquid chlorine, and many another piece of scientific research and achievement which now benefit mankind. They have successfully fought epidemics of many kinds and in many quarters of the globe.

The school developed by the Army Medical Department at Carlisle Barracks is, we believe, proving itself one of the Army's worth-while gifts to the whole country. It is worthy of inclusion in the above roll. If by its teachings it can prepare medical officers more efficiently to care for soldiers in the field, to prevent disease and injuries wherever possible, and to cure them when they have been unavoidable, it will have accomplished a noble mission. When such mission is one that intimately concerns every household in the land, it is of supreme importance indeed. To the end that our men may be the better protected, the Medical Field Service School devotes its every energy and its every thought. Its personnel are mindful of the full purpose of the school's motto: "To Conserve Fighting Strength." These words are not merely worn on the badge of the school that forms a part of its personnel's uniform. They are deep set into the conscience of every man connected with this seat of learning on which so much now depends.

Fig. 13.—Coat of arms of the Medical Field Service School.

THE MANAGEMENT OF THORACIC WAR INJURIES*

James H. Forsee, M.D., Lawrence M. Shefts, M.D., Benjamin Burbank, M.D., Leo J. Fitzpatrick, M.D., and Thomas H. Burford, M.D., U. S. Army

THE management of thoracic injuries has always constituted a serious and significant problem. The frequency of chest injuries and the attendant high mortality demand more than passing attention. Berry,[4] in quoting Hoche's review of 11,000,000 wounded in World War I, stated that thoracic wounds were third in order of frequency and the mortality of this group was 56 per cent, whereas the total mortality was only 8 per cent. Further, in reviewing the cause of death among 12,350 killed, Hoche found that thoracic injuries accounted for 20 per cent and was second only to head injuries. DeBakey,[14] in his excellent collective review, quotes Sauerbruch, Crafoord, Trueta, and Loeffler as finding the frequency to be from 12 to 40 per cent. Such frequency and mortality justify a serious and detailed consideration.

That a considerable proportion of deaths occur near the scene of the trauma is evidenced by Duval's statistics, as quoted by DeBakey.[14] He found that the mortality decreased progressively from advanced aid stations to base hospitals, being 30 per cent at aid stations and 15 per cent in base hospitals. The one factor which can and will reduce such fatalities is the earlier definitive treatment by surgeons trained in the management of thoracic injuries. To effect this it is necessary, in the mobile war now occurring, to have an equally mobile system of evacuation and treatment, flexible enough to meet casualties soon after the injuries are incurred. This entails first, the special training of surgeons and their assistants in the care of chest wounds, and second, an organization whereby they are available on short notice to function in properly equipped medical installations at the point of maximum casualties close to the battle front.

The success of such an attempt in reduction of mortality depends largely on the ability of the personnel and the proper functioning of the medical installations in which they work. Surgeons especially trained in thoracic surgery not only must be used in carrying out the necessary surgery but also as instructors in training general surgeons in the immediate care of thoracic injuries. There are too few specialists in thoracic surgery of field age available. This deficiency can be remedied by the training of general surgeons in the fundamentals of thoracic physiology. This training could best be carried out in hospitals where chest cases would be concentrated. Such centers would also permit training in bronchoscopy and would make possible the training of anesthetists in the technique of endotracheal anesthesia. We feel that as the advent of endotracheal positive pressure anesthesia has been a very important factor in the great advances of thoracic surgery in the last decade, it can be an equally important

*From the Second Auxiliary Surgical Group, Lawson General Hospital, Atlanta, Ga.

factor in the decrease of mortality in war wounds of the chest. Such a program would fulfill the necessity for early definitive treatment by trained personnel.

The second factor involved is one of time and distance. Reduction of the interval of time between injury and definitive treatment resolves itself into either having the surgeon immediately available to the fast changing mile-devouring fronts or having rapid evacuation of the wounded by airplane or motor to the surgeon.

A program of early definitive treatment by trained personnel as outlined above will not only reduce mortality of thoracic injuries but also decrease morbidity, reduce the number of days of hospitalization, and eliminate a large number of chronic empyema cases which linger on long after the war is over and which are the obvious result of treatment usually applied late and incorrectly. The elimination of such a large group, requiring hospital care for many years, would be economically sound.

The more important problems concerned in a presentation of the management of thoracic injuries include a discussion of the relation of wounds to types of projectile, shock, hemorrhage, open pneumothorax, tension pneumothorax, interstitial pulmonary emphysema, massive collapse of the lung and contrecoup injury, "blast lung," ecchymotic mask, cardiac concussion, wounds of the heart and pericardium, cardiac resuscitation, acute and chronic empyema, foreign bodies, combined abdominothoracic wounds, chemotherapy, and anesthesia in thoracic injuries.

RELATION OF TYPE OF PROJECTILE TO WOUND

The steel-jacketed small caliber bullet, as used in small arms fire, will result in a perforating wound. Although the path of the bullet from point of entrance to point of exit may be very bizarre, ricocheting far from its original line of entry, the wound caused is not of the type produced by high explosive. Its long and narrow path is marked by a coagulated and seared trail. However, in injuries from shrapnel, high explosive artillery shells, hand grenades, bombs, or debris of falling buildings, large lacerated wounds of the chest result with serious prognosis.

In receiving casualties from a given sector, the knowledge of the type of small arms used and the type of high-explosive shells laid down by the artillery can usually be ascertained; this knowledge is important in planning the care of casualties already present as well as preparing for the expected additional wounded.

SHOCK

When a patient is first seen with a chest injury, it is often difficult to determine whether the shock present is due to hemorrhage or to a disturbance in the cardiorespiratory mechanism. In such cases any obvious source of hemorrhage must be immediately controlled, and heat and oxygen therapy must be promptly administered. Such conditions as sucking wounds of the thorax or rapidly progressing tension pneumothorax will produce the symptoms of marked shock. Numerous fractured ribs approaching the "stove-in chest" or "hinge fracture" with its many anterior and posterior fractured ribs should be immediately immobilized. The correction of the abnormal mobility of such a chest will

rapidly decrease the intensity of the shock. The simplest and often the most efficient immobilization is the circumferential strapping of the lower costal margin, as advocated by Blades.[6] A rapidly decreasing vital capacity as the result of pulmonary collapse from bleeding into the pleural cavity can simulate the complete clinical picture of shock. The reduced vital capacity has as a result a proportionate anoxia. The resultant shock is generally not due solely to blood loss into the pleural cavity but to the sudden decrease of vital capacity associated with mediastinal shift. In such instances the patient should be placed in a semisitting position, since he is usually more comfortable and can breathe more easily in this position. The same position should be used following treatment for any condition wherein the vital capacity has been decreased. Vital capacity is often further decreased by reduced respiratory excursion resulting from pleural pain, the most common cause of which is fracture of the ribs.

The treatment of shock in chest injuries requires the same close attention as it does in other injuries producing shock. Plasma transfusions are especially valuable in correcting hemoconcentration wherein actual blood loss has not been marked. In chest injuries, however, immediate attention must be given to correcting the abnormal thoracic physiology. A sucking wound of the thorax must be closed, a tension pneumothorax must be relieved, and hemorrhage from intercostal or internal mammary vessels must be controlled. Morphine is indispensable for the relief of pain in combating or preventing shock. It is also important to remember that considerable loss of body heat occurs in open wounds of the chest and immediate closure is the only effective control.

HEMORRHAGE

Hemorrhage in thoracic injuries not involving the heart is from one of three sources; chest wall, parenchyma of the lung, or from the large vessels at the hilus of lung. A hemothorax may occasionally occur from contusion of the chest.

Severe hemorrhage from the chest wall arises from either the intercostal or the internal mammary vessels. When circumstances do not permit a careful exposure of a bleeding intercostal vessel, two circumcostal sutures including the rib, placed above and below the bleeding point, may suffice. In this connection the anatomic position of the intercostal vessel should be recalled. The intercostal artery medial to the angle of the rib is approximately in the center of the intercostal space, and from that point anteriorly the vessel progressively approaches the inferior border of the rib above so that from the angle of the rib forward the vessel is under the edge of the rib in the subcostal groove and simple circumcostal massive suture may be insufficient. In hemorrhage from the internal mammary artery it is imperative to ligate both ends of the lacerated vessel since hemorrhage can occur from either end. The vessel is located approximately one-half inch lateral to the edge of the sternum. Exsanguination may occur in a few hours from unchecked hemorrhage from the internal mammary artery. Hemothorax in which there is no lesion of the chest wall or parenchyma of the lung may occasionally be caused by contusion of the chest.

Hemorrhage due to injuries of the parenchyma of the lung will often be associated with a pneumothorax and a hemopneumothorax will result. In the absence of fractured ribs or wounds in the region of the intercostal or internal

mammary vessels it may be assumed that the etiology of a hemopneumothorax is parenchymal bleeding. Hemoptysis may or may not occur. The immediate effect of parenchymal bleeding into the pleural cavity will be a compression of the lung and the compression often stops the bleeding. The after treatment of hemothorax once the hemorrhage has stopped resolves itself into any method that will re-expand the collapsed lung. There are in the main three schools of thought: first, energetic aspiration repeated often enough to keep the chest dry; second, watchful waiting in which aspirations are performed only to relieve cardiorespiration embarrassment; third, a line of treatment that is somewhat midway between the two. This consists of aspirations (not primarily aimed at keeping the chest dry) and of partial replacement with air. The first has the advantage of removing an excellent culture media, but it has the disadvantage of possibly reviving the hemorrhage due to the high negative pressure resulting from removal of a large amount of blood without replacement with air. The second is advantageous only in that less exertion is necessary in treatment. It has the definite disadvantage of a long period of hospitalization awaiting absorption of blood and re-expansion of the lung with the probability of a resultant fibrothorax, and prolonged chronicity. Further, should infection develop it would occur in a large pleural space and a total empyema often results. The third method is repeated (after seventy-two hours) with partial replacement by air. The aspirations are so spaced as to empty the pleural cavity of blood gradually. The air replacement should be controlled by noting the intrapleural (pressure) readings as recorded on a pneumothorax apparatus. If such an apparatus is not available, air may be replaced in a proportion of 50 per cent of the fluid removed. This was popularized by Morelli[39] in World War I.

Severe lacerations of the parenchyma, especially those extending into the hilus and involving the large vessels, may necessitate lobectomy or even total pneumonectomy. These will most often be associated with large open wounds of the chest and will be available to actual inspection. If adequate facilities are available and the condition of the patient permits, individual ligation lobectomy, as described by Blades and Kent[7] should be done. If hemorrhage is massive and the condition of the patient does not permit a lengthy operation, then massive tourniquet ligation is indicated. It seems probable that lobectomy will be employed with greater frequency in the early management of severe pulmonary injuries, and if properly employed, will, it is believed, be highly successful.

OPEN PNEUMOTHORAX

Trauma to the chest resulting in open wounds exposing the lungs is not always fatal. The same may be said of bilateral open wounds. Graham[16] and Bell proved experimentally that a wound exposing the pleural cavity could be tolerated if the amount of air entering the wound was not greater than the difference between the tidal air and original vital capacity. Thus the important factors are the size of the wound and the original vital capacity. The lung on the injured side does not collapse to a point wherein it is nonfunctioning when it is exposed to atmospheric pressures even when the pleural cavity is free of adhesions. During the respiratory cycle the pressures exerted on the exposed lung are not always atmospheric. The thorax is a flexible moving container during

the respiratory cycle, and there may be even negative pressures in the exposed side during inspiration.[18] This permits a rush of air through the glottis in answer to the negative intrapulmonic pressure occasioned by the enlargement of the chest on inspiration. Thus, if difference of pressures permit of the entrance into trachea of amounts of air to answer the tidal air requirement, the patient will not die of asphyxia. There is also the factor of interference with function of the contralateral side. In the healthy person the mediastinum which is free of adhesions and is not stiffened by previous inflammatory involvement permits transmission of pressures through it so that almost identical pressures may be found in both pleural cavities. Thus the decrease in vital capacity from an open wound of one side of the chest arises from both lungs. This has the practical effect of a tolerance of larger wounds in persons with a stiffened mediastinum.

If the amount of air entering the open chest wound during each inspiration is large enough to interfere with intake of the tidal air requirement, asphyxia will occur. In such cases an interesting and vicious chain of events ensues immediately. There is an initial decrease in vital capacity. The exposed lung will move to the degree that the mediastinum shifts with each unopposed inspiration and expiration of the contralateral lung. This resultant mediastinal shifting increases in rapidity as anoxia from the initial reduction in vital capacity becomes more marked. This shifting is termed "mediastinal flutter." Such shifting will have a direct effect on the right side of the heart. Since the base of the heart is fixed as compared to the apex, it will permit considerable movement of the apex. This shifting on the base follows the rapid fluttering of the mediastinum, and kinking of the large vessels entering the right side of the heart will ensue. Anoxia further is increased by the phenomena of pendulum respiration. On each expiration the air from the contralateral lung with its predominant carbon dioxide content is only partially exhaled, and part goes over into the main and secondary bronchi of the collapsed side. On the next inspiration the air taken into the contralateral lung is composed of atmospheric air from the trachea and air with a high carbon dioxide content of the air reaching the contralateral lung. Thus the chain of events starts with a reduction in vital capacity which involves both lungs, and each step further decreases it. The shifting mediastinum interferes with the proper filling of the right side of the heart, the progressive anoxia of pendulum respiration ensues and must be treated as an extreme emergency. To break the chain of events closing the wound of the chest is the method of attack.

The immediate treatment of open wounds of the thorax is simplicity itself. Closure of the wound is imperative. This can be done by gauze pads and adhesive applied so as to make an airtight dressing. As soon as possible it is essential that the wound be closed surgically, for it is seldom that a dressing of such a wound remains airtight for very long. If adhesive and gauze is not available, large safety pins may be used to close the wound. At the time of the dressing any obvious foreign bodies should be removed from the pleural cavity, and all foreign bodies should be removed when the wound is later closed surgically.

The essential point is that the open pneumothorax must be converted into a closed pneumothorax. The test of the efficiency of the emergency closure is the absence of the sucking noise accompanying respiration.

If the parenchyma of the lung is lacerated, closure of the wound of the chest will convert the open pneumothorax into a progressive tension pneumothorax. This then poses a problem in field conditions, for once the wound has been closed it is necessary to provide an outlet from the pleural cavity which is equal to, or greater than, the opening of the lung into the pleural cavity. This outlet must be a one-way valve, permitting the escape of air from the pleural cavity to the outside. This is accomplished by closure of the wound and installation of a catheter into the pleural cavity and connection of the catheter to a water-seal bottle. The water-seal bottle should always be kept below the level of the chest. No complicated apparatus is necessary, for under local anesthesia through a skin incision the catheter may be introduced into the pleural cavity through an intercostal space. If the patient is to be transported a considerable distance, the water-seal bottle may be too cumbersome and a rubber flutter valve may be substituted. Such a flutter valve may be made by slitting the finger of a rubber glove so that a flap is produced. If it is feasible to close the wound surgically shortly after it occurs, and if the lung is lacerated to a degree that simple suture is insufficient and the patient's condition precludes lobectomy, the lacerated portion of the lung may be sutured into the wound. This may tide a patient over a critical period and more definitive surgery may be done later under more favorable circumstances.

It will bear repetition that treatment of the accompanying shock, position of patient, oxygen, warmth, plasma transfusion, and sedation is essential.

TENSION PNEUMOTHORAX

Tension or pressure pneumothorax is the result of a pleuropulmonary connection.* This connection is the result of rupture of the parenchyma, and the tear acts as a one-way valve which permits the entrance of air from the parenchyma into the pleural cavity. There is no opening for the air to escape through an intact chest wall and the pressure in the pleural cavity will rise progressively. The rapidly progressing tension pneumothorax causes marked dyspnea and all accessory muscles of respiration are utilized. Cyanosis becomes prominent as the mediastinal shift causes interference with heart action and the veins of the neck become prominent. Dyspnea and further reduction in vital capacity result from mediastinal displacement. The displacement is away from the involved side. The patient sits in a semierect position, and as the dyspnea increases, the patient's worried anxious expression is as expected of one fighting for his breath. It is essential to decompress the pleural space immediately. Whether it is necessary to maintain continuous decompression depends on the size of the pleuropulmonary opening. Repeated decompression by needle aspiration may suffice, but if aspirations have to be repeated for more than once daily, it is probably far safer to install a continuous decompression. In injuries occurring on the battlefield the average case has a greater margin of safety by this method. This may be done by introducing a large bore, Nos. 14 to 16 gauge

*A tension pneumothorax may also result from a pleurocutaneous wound.

needle, into the pleural cavity, strapping it in place, being careful not to obstruct the lumen of the needle. If such needles are not large enough to accomplish decompression, an intercostal catheter connected with an under water-seal bottle must be used. Besides the patient's obvious dyspnea and cyanosis, a constant check on the efficiency of the decompression is the position of the trachea as palpated in the neck. As decompression is accomplished, the trachea resumes its midline position from its displacement away from the side of the tension pneumothorax.

INTERSTITIAL PULMONARY EMPHYSEMA

Spasm of the glottis is a reflex mechanism of sudden compression injury to the chest. As a result, air is trapped in the lungs and compression of the chest raises the intrapulmonic pressure suddenly, and rupture of alveoli in the parenchyma of the lung occurs. The pumping action of respiration forces air out into the interstices of the parenchyma. The air travels along the branches of the bronchi and blood vessels, ascending to the hilus and thence up the mediastinum.[14] The appearance of subcutaneous emphysemas at the base of the neck may be the first indication that such a condition exists. Roentgenograms will reveal presence of air in the mediastinum. This condition may be found in absence of any pneumothorax, fractured rib, or hemothorax. This condition has been noted in patients suffering from severe asthmatic attacks.

Treatment consists of watchful waiting. In most instances spontaneous recovery results. It is essential to note whether or not there is extension of the emphysema from the base of the neck outward to the shoulders, up into the neck, and down onto the chest. If this extension is present, then it is evident that this is acting as a decompression, thereby relieving the pressure in the mediastinum. If the air does not disperse itself as described above, the pressure will rise in the mediastinum and tend to compress the large veins. This will interfere with filling of the right side of the heart and obvious distention of the neck veins will occur. Simply marking on the skin each day the progress of the emphysema is a sufficient guide. If the neck veins become distended, and there is no increase in subcutaneous emphysema, then a mediastinotomy is in order. Mediastinotomy carried out just medial to the lower end of the sternomastoid muscle entering into the superior mediastinum will usually suffice.

MASSIVE PULMONARY COLLAPSE AND CONTRECOUP INJURY

Massive pulmonary collapse occurring as a result of trauma to the chest may involve all the lobes of one lung, but more often it involves one, or at most two, lobes. This condition may also result from trauma to the abdomen. In either trauma to the abdomen or chest the actual amount of trauma may be relatively insignificant. Collapse may occur from pressure effects of bomb or shell explosives. In cases of direct trauma or pressure effects of explosions, a contrecoup collapse may occur with only minor involvement of the homolateral side. The mechanism of massive pulmonary collapse is obscure. One theory is that it is a reflex inhibition of movement of the chest wall with interference of the usual aeration.[47]

Clinically, the patient will present far more dyspnea than one would expect from collapse of one lobe. Cyanosis even though more than expected is not as

marked as the dyspnea. The trachea is found deviated to the side of the collapse. Cardiac dislocation toward the affected side will usually be found. Sudden rise in temperature from normal to 103° or 104° F. is also a common finding. Physical findings of a nonaerating lobe or lobes will be found. Following spontaneous aeration or in areation following treatment, râles will appear, and in spite of roentgenologic evidence of good aeration and disappearance of the dyspnea and cyanosis the râles may remain for several days.

Treatment is directed toward reexpansion of the involved lobes. Use of carbon dioxide is recommended to increase the depth of respiration. The patient should be turned with the involved side up and made to cough at five- to ten-minute intervals. If coughing is weak and ineffectual, intubation may be carried out without moving the patient from the bed. A curved semirigid rubber catheter (McGill) may be inserted directly into the trachea, and sudden suction of considerable intensity should be applied to the catheter. During the intubation the patient will often cough strenously enough to aerate the lobes involved. If these measures fail, then bronchoscopy should be carried out to remove mucus from all bronchial orifices. Such endoscopy should be done under local anesthesia and without anesthetizing the vocal cords or trachea. In a surprisingly large number of cases the collapse will disappear following bronchoscopy wherein only small amounts of mucus are aspirated from orifices of bronchi to the involved lobes. It is imperative that treatment be immediate and energetic. Permitting such a collapse to persist will, in the majority of cases, result in pneumonic consolidation. If there is any question of the persistency of the collapse, prompt use of sulfonamide drugs will often prevent an otherwise serious pneumonia. It is felt that the majority of postoperative pneumonias are preceded by some degree of similar collapse.

BOMB BLAST ("BLAST LUNG")

Mass bombing with high explosives has accentuated the importance of blast injury to the lung. Zuckerman and his coworkers,[53] through an extensive series of experiments, have shown that the injury is due to the direct impact of the wave upon the chest wall. Lesions have occurred even when the suction component was excluded.

Experimental animals subjected to the detonation of high explosives show the following sequence of events: There is an initial fall in blood pressure which is ascribed to shock from trauma. Those animals who survive this initial shock, but develop pulmonary lesions, reveal a lowered blood pressure and marked dyspnea. These effects are due to the parenchymal changes, which result from the sudden compression of the chest wall by the wave of high pressure, which simultaneously retards expulsion of the air through the trachea. As a result, the delicate alveolar tissues are ruptured. At the same time the reserve of the pulmonary capillary bed is reduced.[37] Wearn has shown that reduction of this, especially when accompanied by an increase in the blood volume, results in an increase of the intrapulmonary pressure and subsequent fall in the systemic pressure. If the available capillary reserve is reduced to the point where it is insufficient for even the resting venous return, pulmonary edema will result.

Pathologically, the most persistent finding in these animals was multiple areas of hemorrhage in the parenchyma of the lung.[54] These hemorrhagic areas

are most common along the line of ribs, suggesting that these have been driven forcibly against the lungs with resultant contusion. Microscopically, the typical lesions consisted of rupture of the alveolar wall, with hemorrhages originating from the torn alveolar capillaries. The alveoli and smallest bronchioles were filled with blood. Where hemorrhage was severe, frequently there was collapse of the corresponding lobe.

The findings in clinical cases of blast injury are very similar in all respects to those of the experimental animals. Many patients who died had no evidence of external injury and just showed blood-stained froth in the mouth and nose. Post-mortem examination revealed the pulmonary hemorrhages and torn alveolar structures. In patients who have survived the initial blast, there is evidence to indicate that there occurs a diapedesis of red blood cells from intact capillaries which is progressive and lasts for as long as fifty-one hours.[23, 24] Those patients who survived presented the following clinical features: Shock was evident in all and profound in many. Dyspnea was universal, but in many cases did not become very evident until forty-eight to seventy-two hours following the injury.[13] Cyanosis was present in all cases and was proportionate to the degree of injury. Chest pain was of two types, a constant, deep central type and lateral pain which was associated with the respiratory movements.[42] Abdominal pain and rigidity was the predominant finding in some cases, but each case subjected to laparotomy failed to disclose serious intra-abdominal injury. Hemoptysis was not frequent, but blood-stained sputum was common. Cough and expectoration were absent in the first twenty-four hours but invariably appeared thereafter. Rupture of the eardrums was practically pathognomonic.

Physical signs were very meager. A universal finding was the "ballooning of the lower part of the chest."[42] The thorax was apparently one-half to three-fourths distended and fixed in the position of inspiration. Percussion resonance was usually normal. Breath sounds tended to be distant and râles were variable. X-ray examination was of great help in establishing the diagnosis. The typical picture consists of bilateral mottling of the lung fields, resembling a patchy bronchopneumonia, which usually clears in seven to ten days.[42]

It should be noted that in bombing casualties, not all persons in whom there is no external evidence of injury die from the direct effects of blast. Indeed, the English observers emphasized that more people die from such indirect effects as asphyxia, carbon monoxide poisoning, injuries sustained from being trapped in collapsing buildings, and injuries from missiles. The diagnosis of true blast injury of the lung rests upon a reliable history, the presence of shock in the absence of any external injuries, and the development of serious respiratory difficulty.

Treatment of this condition is based upon the foregoing observations. Absolute rest is imperative and should be continued until x-ray examination reveals complete clearing of the lung fields. Oxygen is essential in most cases. In the presence of venous congestion and pulmonary edema, venesection may be a life-saving procedure. Abdominal laparotomy should not be undertaken unless positive proof of intra-abdominal injury is obtained. Any operative procedure should be delayed as long as possible. Transfusions and intravenous fluids are definitely contraindicated. Zuckerman has shown that chests which are well

padded are protected from blast injuries.[54] This obviously proves the necessity for air raid shelters. In the absence of such protection one should assume the prone position, especially behind some substantial structure.

ECCHYMOTIC MASK

A unique condition is "ecchymotic mask," a bluish-violet discoloration of the upper portion of the face and neck extending downward to include the upper portion of the chest which results from sudden direct compression of the chest or abdomen. An excellent consideration of this subject has been written by Heuer.[27] In civilian life it has most often been seen following compression of the chest between the rear end of a truck and a loading platform. Sudden direct compression of the extremities while the patient falls, or is thrown with thighs flexed on the abdomen directly, transmitting the compression to the abdomen, may also give rise to this condition. In wartime such compression may occur from falling debris in bombing with the patient actually crushed. The discoloration is usually more intense at the areas of pressure, such as collar bands, hatbands, and suspenders.

The mechanism is that of marked venous stasis in dilated but intact peripheral venous capillaries. There is no evidence of diapedesis. The intact vessels and absence of extravasation found microscopically, and the absence of usual shades of color occurring as an ordinary ecchymotic spot fades is proof of the stasis in intact vessels. The discoloration may also be found in the pharyngeal and buccal mucosa. In these regions, as well as in the conjunctiva and retrobulbar regions, actual hemorrhage may occur.

Clinically, the discoloration starts to fade at about the second day and usually disappears in two weeks. As a rule, patients are not uncomfortable and the majority clear up without sequelae. There may, however, be ocular symptoms, ranging from mild blurred vision to complete blindness. The retrobulbar hemorrhage, or fundal hemorrhage, may result in permanent optic nerve atrophy. Fortunately, ocular involvement occurs only infrequently.

CARDIAC CONCUSSION

Bright and Beck[10] and Warburg[52] have presented excellent reviews of this subject and have come to the following conclusions: Trauma to the intact chest may be indirectly transmitted to the heart. This is especially true in the young adult, for the chest is far more resilient and flexible than in an older person, permitting the striking force to be more damaging to the heart. The type of injury may be a direct blow over the precordial region, anteroposterior compression of chest between two solid objects (as described in section on ecchymotic mask) or a blow to the abdomen causing sudden rise in intra-abdominal pressure. As can be seen from the above types of injuries, one must be on the lookout for cardiac involvement in any compression injury.

Sufficient experimental work has been done to explain the pathologic physiology. Trauma may cause an actual immediate rupture, and death ensues promptly. The majority of cardiac injuries reported which resulted in death consisted of immediate rupture of one of the chambers. Actual contusion may occur, with hemorrhage and softening and eventual cardiac rupture. The contusion with resultant petechial hemorrhages may commonly involve any portion

of the conduction system. However, the most frequent injury is that causing a reflex spasm of the coronary vessels with a syndrome not unlike that of the common coronary occlusion seen in civilian life causing infarction. Immediate hemorrhage near a coronary vessel or conduction system may interfere with the lumen of the vessel or the functioning of the conduction system, respectively.

It has also been proved experimentally that in case of vagosympathetic imbalance or in a heart sensitized by adrenalin cardiac irregularities may not only occur but coronary spasm may more readily result. Therefore, in the heat of battle with the vascular system surcharged with considerable adrenalin slight trauma to the chest may cause considerable cardiac disturbances.

Clinically, the patient may be dazed or unconscious. If there is no immediate rupture, the patient may rapidly recover and have no subjective symptoms for a period of from several hours to several days, at which time precordial pain or discomfort may develop as a result of vascular occlusion, or the usual dyspnea and choking sensation of cardiac irregularities may ensue.

Clinically, a wide variety of syndromes may be expected. In cases of delayed cardiac rupture from actual contusion there may be a period of one to two weeks from time of injury to sudden development of a cardiac tamponade. In instances of hemorrhage in, or adjacent to, the conduction system a number of cardiac irregularities may result. Ectopic contractions, auricular fibrillation, and auricular flutter may occur. Various types of heart block have been reported. The latter have been found in absence of any marked demonstrable cardiac damage.

The basis of treatment in this type of injury is the recognition of the latent interval between injury and actual infarction and between injury and cardiac rupture from contusion. In all cases of injury to the chest as described above a regime of rest and sedation should be carried out and continued as in cases of coronary occlusion. Absolute and complete rest must be continued for a minimum of at least three weeks. In those cases of chest injury wherein cardiac irregularities are detected then a suspicion of cardiac injury becomes a certainty, and complete and continued rest is essential. Surgical intervention in case of rupture after the latent period is not as successful as in cases of penetrating injuries to the heart, because in cases of rupture due to vascular occlusion the area involved is much larger and adjacent muscle is usually very friable.

PENETRATING WOUNDS OF THE HEART AND PERICARDIUM

Penetrating wounds of the heart occur relatively rarely in civilian practice. This statement is based on Bigger's[5] report of such cases constituting only 0.1 per cent of the surgical cases at the Medical College of Virginia Hospital and Boland's[8] report of 1.4 per cent of 1.187 cases of penetrating wounds of the chest. These statistics represent only those patients who live to reach a hospital and do not represent the true total number of cases. Many probably die promptly from an extremely rapid tamponade because the wound of the myocardium is so placed as to cause massive bleeding.

In instances of bayonet wounds or wounds caused by small caliber bullets, the hemorrhage into the pericardium may be such that the cardiac tamponade will occur slowly enough to permit surgical closure. Cardiac tamponade presents

a syndrome of a progressive dropping of systolic pressure, rising venous pressure with distended neck vein, quiet distant heart tones, and increase in area of cardiac dullness. Repeated aspirations of the pericardium may be done to tide a patient over until surgical closure is accomplished. Aspiration of the pericardial cavity may be accomplished by inserting a needle in the angle between the xyphoid process and the adjacent left costal arch. The needle is directed cephalad inward and toward the left at approximately an angle of 45 degrees. Surgical repair may be accomplished through a curved incision exposing the third, fourth, and fifth costal cartilages, resection of sufficient portions to expose the pericardium, opening of the pericardium, and suture of the wound of the heart. It is essential to use positive pressure anesthesia. Technique of such closure has been fully described by Elkin[15] and Beck.[1]

CARDIAC RESUSCITATION

The problem of cardiac standstill, formerly assumed to be a problem handled only by the surgeon in a meticulously fitted operating room, is now because of war casualties a problem of all physicians wherever and whenever it occurs. Cardiac cessation results either from failure of the sinus node or as an end result of ventricular fibrillation. By far, the former is the most common cause. The idea of reviving the human heart, when its action is stopped, is feasible, as shown by Koontz,[36] who by perfusion experiments revived 65 of 127 hearts, whose action had stopped for a period of two hours. Forty-eight of these 65 (73.8 per cent) developed a regular heartbeat.

An outline for resuscitation is suggested as follows:

I. Essential factors in treatment of all cases
  - A. Unobstructed airway
  - B. Artificial respiration
    - 1. Manual
    - 2. Mouth-to-mouth insufflation
    - 3. Mechanical respirators

II. With intact abdomen and chest
  - A. Blow to precordium
  - B. Direct stimulation of heart
    - 1. Needle in right auricle
    - 2. Injection of epinephrine
    - 3. Electrical stimulation via the needle
  - C. Massage of heart
    - 1. Through emergency laparotomy, massage conducted through an intact diaphragm
      - (a) Massage through an opening of the diaphragm

III. During thoracotomy
  - A. Massage of the heart
  - B. Use of electrical stimulation or drugs, as indicated by topical application

IV. During laparotomy
  - A. As under II. C

In any treatment of cardiac resuscitation the maintenance of proper oxygenation is imperative. Irreversible cerebral damage can occur within five to eight minutes in the presence of anoxemia. Proper oxygenation can be achieved and maintained only by assuring the immediate institution of an unobstructed airway and artificial respiration.

The problem of an unobstructed airway is essential to proper oxygen exchange. Removal of foreign body obstruction in the upper respiratory tract with the jaw held up and forward will usually suffice. The unconscious patient will not often present a spasm of the glottis, but if this does occur intubation is essential.

Artificial respiration should be started immediately. This may be accomplished by the Schaefer prone method, mechanical respirators, or even mouth-to-mouth insufflation. The important fact is that one should not await the assembling of an armamentarium sufficient to cope with the condition before starting artificial respiration. The mechanical expansion and collapse of the lungs directly helps to stimulate the heart. This has been clearly demonstrated by Thompson, Birnbaum, and Shiner[49, 50] by the phenomena of "asphyxial resuscitation." The mechanical respirators, utilizing a positive and negative pressure, are excellent when available, and if intubation is necessary, complete control of respiration is assured.

In cases of cardiac standstill occurring with an intact abdomen and chest, as soon as an obstructed airway and artificial respiration are obtained, sharp blows to precordium may induce cardiac contraction (Cordelli[12]). This is, of course, unreliable, but may be done quickly while other measures are being started. Immediate stimulation of the right auricle by a needle is next in order. Mere mechanical stimulation of the right auricle may induce contraction. It is important that the irritation occurs in the auricle. Hyman[29, 30] has shown that the "action current of injury" may produce flutter followed by fibrillation. As fibrillation of the ventricles is conceded incompatible with life, it is, therefore, necessary that the needle be inserted in the region of the right auricle. A needle about 4 or 5 inches long inserted in the third or fourth intercostal space at the edge of the sternum, directed inward and slightly caudad, will approach the approximately correct position. If mechanical irrigation does not succeed, then injection of 1 c.c. of 1:1,000 epinephrine into the right auricle is next in order. The institution of all the above can be accomplished in from eighty to one hundred and twenty seconds. Next, electrical stimulation utilizing principles as elucidated by Hyman[31] and Beck[2] may be conducted per needle. Application of electrodes directly to the heart are, of course, far more efficient. Use of ordinary electric light current, with a resistance coil to decrease the amperage to one or one and one-half amperes, may be used.

If all these measures fail, at the end of eight minutes, then massage of the heart should be instituted. Opening of the abdomen through an incision in the epigastrium large enough to admit a hand should be accomplished promptly. The patient is to all intents and purposes dead and will most assuredly remain so unless cardiac action is started. Massage is then done by pushing the heart against the anterior chest wall through the intact diaphragm. If no contractions have occurred after sixty seconds, the diaphragm and adjacent pericardium

should be opened, and with the thumb directly on the heart, and the fingers outside the diaphragm, good massage can be accomplished. This method, with the technique of opening the diaphragm just behind the xyphoid process, between the attachments of the two sides of the diaphragm through the avascular area is described by Nicholson.[41]

In instances of cardiac standstill during thoracotomy, direct massage of the heart is by far the best method.[2, 30] Application of Hyman's pacemaker,[31] or Beck's electrodes[2] can be used under direct vision.

The problem of ventricular fibrillation is essentially one of stopping cardiac motion by shocking it into standstill, and then reshocking it into a more normal action.[2, 30] Calcium gluconate intravenously may be used to decrease the sensitivity of the heart, and sodium iodide may be used intravenously to increase the sensitivity, with resultant cardiac motion.

The foregoing suggested outline of treatment may be utilized at advanced medical installations. In all cases of casualties, without obvious cause of death, and with no discernible heart action, immediate energetic action may truly be lifesaving. The mere establishment of an unobstructed airway, institution of artificial respiration, and mechanical stimulation of the right auricle with a needle, may, if done promptly, revive seemingly hopeless patients.

ACUTE EMPYEMA

Acute empyema during the early part of the influenza epidemic of 1917-1918 treated by early open drainage carried an average mortality of 30.2 per cent.[18] In some camps it reached 90 per cent.[44] As a result of the investigation of Graham and Bell,[18] certain principles were elucidated, and treatment of empyema based on those principles reduced the mortality to 4.3 per cent. In view of present war conditions and the possibility of the outbreak of epidemics of influenza with streptococcal pneumonias and resultant empyema, the principles outlined by Graham and Bell should be reviewed, in order that we may not repeat the errors made during World War I.

The principles are: (1) Drainage, but with the careful avoidance of an open pneumothorax during the period of active pneumonia; (2) early sterilization and obliteration of the cavity; and (3) maintenance of nutrition of the patient.[19] The fact that the majority of the patients in army camps died as a result of an open pneumothorax (operative) during the period of an acute pneumonia was the basis for the investigation which resulted in the change in the method of treatment. During the period of acute streptococcal pneumonia, which was so prevalent in the army camps, the vital capacity was markedly lowered, and the patient was then subjected to an additional lowering of vital capacity by the establishment of an open pneumothorax. When this plan of treatment was followed, the mortality was exceedingly high. As a result simple aspiration during the pneumonic stage was substituted.[18] This was done as often as every three to four days. However, dyspnea from accumulation of large amounts of pleural fluid must not be permitted to occur. When the patient has recovered from the stage of acute pneumonia and the empyema is localized in one portion of the pleural cavity and the pleural fluid removed is frank pus, open drainage can be safely performed. By this time, the vital

capacity has greatly increased. The changing character of the fluid is a good index of what is occurring, and when it has definitely changed from a thin, slightly cloudy fluid to frank, thick pus, one may rightly feel that there is a considerable stiffening of the mediastinum and adequate drainage of the empyema should be accomplished.

Both the intercostal catheter drainage and drainage by rib resection have their advocates, and satisfactory results are obtained by the proponents of each method. The important consideration is the appreciation and application of the principles involved in the proper treatment of acute empyema rather than dogmatic statements about a particular method. The avoidance of an open pneumothorax during the acute stage of the pneumonia is of paramount importance. Adequate drainage of the localized empyema must then be instituted.

Obliteration of the cavity is a fundamental principle of treatment. Chemical sterizilation by irrigation every two to four hours with Dakin's solution liquefies the necrotic material and permits it to drain more readily. No chemical can sterilize a cavity without completely free drainage. Recently, it has been shown that the addition of solutions which lower surface tension to Dakin's solution, aids the latter in the liquefying process and tends to enhance its sterilizing qualities. Such detergent substances have been described by Petroff and Schain.[43] The cavity should be measured daily, if a bronchopleural fistula is not present, and the tube must not be removed until the cavity measures less than 10 c.c. The removal of the tube before the cavity is obliterated is an important cause of the development of chronic empyema. The maintenance of the nutrition of the patient by the intake of a high calorie and high vitamin diet supplemented by blood or plasma transfusions is essential.

CHRONIC EMPYEMA

Chronic empyema must of necessity be mentioned in any discussion of war injuries, for the majority result from ill-timed and poorly planned early treatment. Keller,[33] in reporting on a large series of chronic empyema following World War I, found that 75 per cent had accessory pockets, 15 per cent had foreign bodies (drainage tubes and bismuth paste), and 90 per cent had osteomyelitis of the ribs. These were all residual cases in which hemolytic streptococci were found. Too early open drainage was done in a vast majority of instances instead of awaiting localization of the empyema. Many cases, therefore, suffered a total empyema to start with, and of these the majority had inadequate drainage so that pockets developed and remained. If the principles of treatment as outlined in the section on acute empyema are followed, there will not be a large group of chronic empyemas following World War II. For detailed consideration of chronic empyema, the reader is referred to the work of Keller[33] and Graham.[19]

FOREIGN BODIES

In any operative procedure wherein the pleura is explored, all foreign bodies should be removed. In the emergency treatment of sucking wounds of the chest, the removal of foreign bodies should be secondary to immediate strapping of the wound. In such instances the foreign body can be removed during the surgical closure.

In general, foreign bodies in the parenchyma should be removed. However, the mere presence of a foreign body in the parenchyma is not alone an indication for its removal. Foreign bodies lodged in the pulmonary parenchyma in patients who have recovered and are apparently well should be studied carefully in base hospitals, and the treatment must be individualized. As a rule, if the foreign body is a single bullet, there is less chance of it eventually causing complications, than if the foreign bodies are shrapnel, shell fragments, or multiple splinters. Retained foreign bodies often result in late pulmonary suppuration.

In any condition causing prolonged pulmonary suppuration, surgeons should become foreign-body conscious. Drainage tubes are the most frequent offenders. Tubes should be pierced with a safety pin, so that if red rubber radio-opaque tubes are not available, the tube can be located by x-ray. With this in mind, it is well not only to fix drainage tubes securely, but also to state clearly in his medical record the fact that such tubes are used on a person.

COMBINED ABDOMINOTHORACIC WOUNDS

Combined wounds of both thorax and abdomen are not infrequent and they carry a high mortality. In World War I this type of wound was found in 4.6 per cent of all chest injuries.[28] In the Spanish Civil War these wounds constituted 11 per cent of all abdominal wounds. Heyd[29] reported a mortality of 60 to 75 per cent during World War I. From reports of World War I by Gordon-Taylor,[17] prognosis is usually worse if the point of entrance is in the abdomen. Penetration of a hollow viscus, hemorrhage from the spleen or liver, or evisceration are the most common grave possibilities.

The treatment of simultaneous wounds of the chest and abdomen often present a difficult problem. It is desirable to close the thoracic opening before the abdomen is explored through the abdominal wound. This permits the correction of disturbed cardiorespiratory physiology, and the patient's vital capacity will be increased. It is to be remembered that in wounds of the chest the upper abdomen may be spastic and pain may be referred to the abdomen without any involvement of the abdominal contents.[3] In the closure of such wounds it is important to trace the course of the bullet and to inspect the diaphragm. It may be that there is an open wound of the chest with a rigid but intact abdomen in which the contained viscera is involved and the bullet remains in the abdomen. In such cases exploration of a large portion of the abdomen can be conducted through the thoracic wound by merely enlarging the opening in the diaphragm. Certain wounds of the stomach, liver, and intestines can be managed through such an approach. The repair of diaphragmatic tears is essential. The replacement of abdominal organs herniated up into the chest through the diaphragmatic opening helps restore the proper cardiorespiratory physiology. Various techniques for closure of diaphragmatic hernias, as described by Schiffbauer,[45] Harrington,[25] and Truesdale[51] may be used.

CHEMOTHERAPY

Wounds of the chest, like wounds in any region of the body, will respond, to a large degree, according to whether or not infection supervenes. One of the epochal events in medical progress since World War I was the introduction of

the sufonamide drugs. Recent studies have proved this remarkable series of dye derivatives to be valuable in the prevention of infection as well as in the control of sepsis, and to have a local bacteriostatic effect that makes them of paramount importance in the prophylaxis of wound infections. In the present war the role of the sulfonamide drugs in this respect may transcend anything we are prepared to believe with our present limited perspective based only on the more or less ideal surgical circumstances of peacetime experience. A consideration of the sulfonamide therapy of war wounds of the chest, therefore, necessitates a discussion of both the systemic and the local application of the drugs. For the present, the accepted representatives of the sulfonamide group for surgical purposes are sulfanilamide, sulfathiazole and sulfadiazine.

The remarkable reduction in infection rate in a series of compound fractures, published by Jensen and others in 1939,[32] treated by the local implantation of sulfanilamide, marked a new era in the treatment of wounds, and opened an entirely new vista for this amazing drug group. Their results were quickly corroborated by others. Key and his group[34, 35] carried out experiments, proving that the drug has no deleterious effects on the tissues, and does not delay wound healing. Experience was consistent in acknowledging the marked decrease in wound infections when sulfanilamide was introduced into the wounds. Intrathoracic wounds, however, produced a unique set of circumstances. Here, as in no other region, large, unobliterable cavities are likely to be encountered, and more important, one frequently has to deal with the "open bronchus," which serves as a perpetuating source of virulent, drug-refractory anerobic pathogens. Cognizant of these difficulties, Burford and Graham[11] implanted the drug in a series of total pneumonectomy and pulmonary lobectomy cases. It was found, as expected, that the drug did not prevent the development of an empyema, if the bronchus opened, but that the streptococcal component of the bacterial flora was inhibited and frequently eradicated, and for that reason perhaps the severity of the process seemed frequently less severe. There was some indication that contamination of the pleural space at the time of operation was less likely to result in empyema, if the drug was used, provided, of course, the bronchus did not open. No damage to the pleura or pericardium occurred, and very high hemic concentrations of the drug were promptly obtained.

The exigencies of war surgery will of necessity frequently leave much to be desired from the standpoint of impeccable technique, and trustworthy asepsis. It is here that the sulfonamides will doubtless prove invaluable. It is our belief that any chest wound whether intrapleural or of the chest wall alone should have the benefit of this added precaution, sulfonamide locally, even though contamination is known to be minimal. Never, however, should the anticipated use of the drug entice one into a false sense of security, and a consequent lowering of the standards of proper wound handling.

Whether sulfanilamide or sulfathiazole should be used is a matter that would be easier to decide if one could be sure of the invading microorganism. Sulfanilamide is probably more efficacious against the streptococci, and sulfathiazole is certainly more lethal to the staphylococci. Some prefer to use a mixture of equal parts of sulfanilamide and sulfathiazole.

The amount of drug used will vary with the type and extent of the wound. For example, one gram would be sufficient for a laceration of one or 2 inches of the chest wall and not involving the pleural cavity, while as much as 12 or 15 Gm. could be placed with impunity in the space left by a total pneumonectomy or pulmonary lobectomy. In using larger amounts, it is to be remembered that the drug is absorbed very rapidly, particularly from the pleural space, and high blood levels are reached very quickly. If a large dose is implanted, the development of a methemoglobinemia should be anticipated and properly dealt with.

All those experienced in the local use of the sulfonamides are agreed that it in some unexplained fashion tends to increase the likelihood of bleeding and hematoma formation. Particular care must, therefore, be taken to achieve completely adequate hemostasis. In this regard, it is mandatory to remember that it is usually unwise to introduce the drug into the pericardial cavity, unless contamination has been excessive. Not only does the drug frequently occasion disturbing alterations in cardiac rhythm when dusted on the epicardium, but its use is almost certain to occasion a collection of fluid which may cause a serious degree of cardiac tamponade. If the drug is placed in the pericardial cavity, drainage is obligatory. In all cases wherein large amounts of dye are placed in the pleural cavity, the resultant pleural pressure changes must be carefully observed and promptly adjusted. These dyes act as hypertonic solutions, causing the development of pleural effusions. When the pleural cavity is not drained postoperatively, the occurrence of effusion with accompanying mediastinal shift may cause dyspnea proportional to the amount of the effusion. Aspiration of a sufficient portion to permit the patient to breathe comfortably is indicated. It is unnecessary to empty the chest completely for return to normal dynamics can be effected with removal of only 200 to 300 c.c., when there may be a total of as much as 2,000 c.c. By this method, the majority of the fluid remains with its high concentration, and the effectiveness of the drug is utilized without deleterious pressure effects.

The sterilization of the drug previous to implantation into wounds has been the subject of considerable discussion, and while sterilization is highly desirable, it is not absolutely necessary, and we have no hesitancy in using the unsterilized powder if the facilities for autoclaving are not available. Most of the commercial preparations are now supplied in sterile ampoules.

Once infection has supervened, then, of course, the systemic role of the drugs must be relied upon. In infected wounds of the chest, sulfonamide is promptly indicated in adequate doses just as in infection elswhere. In this regard, we wish to emphasize that the continuance of sulfonamide therapy with the neglect of proper surgical drainage, once pus has formed, can only lead to disaster.

We are certain that the prophylactic administration orally of sulfonamide, preferably sulfathiazole, will do much to minimize or to prevent the development of pneumonitis in cases of pulmonary atelectasis, which are not promptly reaerated. These cases are not infrequently associated with severe chest trauma. It is our practice to give sulfathiazole promptly in all such cases when there is the least doubt that complete pulmonary re-expansion has occurred.

ANESTHESIA

Anesthesia employed in thoracic surgery in wartime may be considered in relation to its use in intrapleural and extrapleural surgery, as well as to its availability in various army installations.

The following can be used in extrapleural surgery: local (novocain), sodium pentothal, ether, nitrous oxide, and oxygen with or without ether and cyclopropane. All the anesthetic agents, except cyclopropane, will be available at evacuation hospitals. Cyclopropane will probably be reserved for the numbered and named general hospitals.

The anesthetics, which can be employed in intrapleural surgery are: cyclopropane, nitrous oxide and oxygen, ether, sodium pentothal, and spinal nupercaine (1:1,500). Nitrous oxide, oxygen, and ether, and sodium pentothal will be used as near the front as necessity requires. Nupercaine (1:1,500) or Jones solution has received more enthusiastic acclaim by the British.

While a trained anesthetist is a boon to the abdominal and orthopedic surgeon, he is an absolute necessity to the thoracic surgeon. A general knowledge of the anesthetic agents and methods of administration usually suffices for abdominal and orthopedic surgery. At least, it may be stated that with a minimum of knowledge untrained personnel may administer anesthetics for abdominal and orthopedic surgery in the press of war. However, anesthetists administering anesthesias in intrapleural surgery must have not only thorough knowledge of the physiology of respirations but also sufficient experience to cope with the many disturbances of the cardiorespiratory mechanism which may occur.

In considering premedication, morphine and scopolamine are the drugs of choice. Many patients will have received morphine sulfate during the first aid treatment and this must be kept in mind in any further premedication. We prefer scopolamine to atropine sulfate because the former has a sedative action that the latter lacks. Soldiers who have had a large meal before trauma or shock occurs, will, because gastric motility is decreased, retain the food in an undigested state. Lavage may be necessary before the anesthetic is started.

Nerve block with novocain can be used in extrapleural procedures. The pain of fractured ribs can be relieved by intercostal nerve block.[46] Large extrapleural wounds are readily managed by local injections. Simple rib resections are easily accomplished under novocain anesthesia. Gas casualties with chest wounds can be readily managed by local anesthesia.

Intravenous sodium pentothal is now a well-established method and forms a valuable adjunct to the anesthetist's armamentarium. Gas anesthesias are widely used. Ether is the most universal. Nitrous oxide, oxygen, and ether makes possible adequate oxygenation by the reduction of the concentration of the nitrous oxide used. It is otherwise impossible to control robust men without some form of anoxia when nitrous oxide and oxygen alone are used. Cyclopropane is particularly adapted to chest surgery because it is given with a high concentration of oxygen. Cyclopropane has nearly replaced ethylene, which is lighter than air and does not give the depth of anesthesia that is possible with cyclopropane.[22]

Proper endotracheal anesthesia has made possible the modern advances in intrapleural surgery. With a carefully developed technique the anesthetist can completely control the patient's entire respiratory cycle and can maintain the proper intrapulmonic pressure at all times.[21] A further very important consideration is that in cardiac standstill the primary factor in cardiac resuscitation is satisfied. Adequate oxygenation through an open airway is thus assured. The special advantages of such a closed system are that it regulates intrapulmonary pressure, controls respirations, and conserves body heat.

Once the chest has been opened, pressures of from +6 to +8 cm. of water are necessary.[40] This maintains sufficient inflation to produce a vital capacity which is above a dangerous level. The amount of pressure should not be a matter of approximation but should be carefully checked by a manometer. The water manometer of Flagg or the graduated weights of Connell are excellent. If these are not available, a simple manometer may be constructed by inserting a measured length of tube into a column of water (Barach). This prevents the raising of the intrapulmonary pressures beyond dangerous limits, even though the bag may be suddenly and forcibly compressed by the anesthetist.

One of the most recent developments has been the use of controlled respirations.[21] It is a great boon to the operator if the patient is under the control of the anesthetist. The rate and depth of respirations can be regulated and stopped and started at the will of the anesthetist. During repair of the diaphragm, manipulation of the mediastinal structures, and suture of the parenchyma of the lung, the movement of the lung may be stopped for a period sufficient to do careful minute work. The technique of controlled respirations, as introduced by Guedel,[21] is reported by Neff and associates for use in thoracic surgery.[40]

In front line surgery it is conceivable that intratracheal anesthesia will not be available. In such instances a tightly fitting face mask will be of value. Any mask with an inflatable cushion will be efficacious (Connell's or McKesson's).

Cyclopropane and oxygen is the anesthesia of choice in intrapleural surgery. The principal advantages of cyclopropane are the high oxygen content, the ease of induction, and the lack of irritation to the lungs and other organs of the body. In our experience there has been little effect on the blood pressure. A rise of over 20 mm. of mercury is the exception. The one disadvantage of cyclopropane is its explosive quality. This is mentioned because it has been overemphasized. Greene states that "Under the same clinical circumstances ether and oxygen, with or without nitrous oxide has the same great tendency toward propagating a wave of flame or pressure through the respiratory tract as has ethylene-oxygen and cyclopropane-oxygen."[20] This is confirmed by the report of the committee appointed by the American Society of Anesthetists to investigate the hazard of fires and explosions due to anesthetic agents. They emphasized that nitrous oxide oxygen and ether is just as explosive as cyclopropane. The principal advantages of ether and air are that it has a relatively small tendency to propagate a wave of flame or pressure down the respiratory tract, even though explosions of ether and air can cause death. By the closed method of administration small amounts of ether are necessary for anesthesia so it is less irritating. This is particularly true when ether is used to *supplement* nitrous oxide and oxygen. Addition of a small quantity of ether enables the anesthetist to increase the oxygen percentage in the mixture. Ether alone or in

gaseous mixtures gives the untrained personnel a large margin of safety so that it is relatively safe. However, ether is still unpleasant to the patient and the induction period is longer than with gases.

Sodium pentothal intravenously with 100 per cent oxygen by the intratracheal McGill tube is a more recent idea in thoracic surgery. Sodium pentothal has been used extensively, and even the most ardent advocates of nitrous oxide are now using sodium pentothal. After the endotracheal tube is inserted, a cocaine spray through the tube is necessary to abolish the bronchial reflexes initiated by the operator's manipulations. It is always advisable to administer oxygen to the patient under sodium pentothal, since there is a gradual depletion of oxygen in the circulating blood.

Regardless of the type of anesthesia, oxygen by the nasal catheter introduced into the oropharynx should be continued postoperatively for a few days. While intravenous fluids are given from the beginning of the operation, plasma and whole blood will be indicated postoperatively; if plasma or whole blood has been given during the operation, they may have to be repeated. Of course, the patient should be kept comfortable with morphine. This should be ordered as the indication arises. At no time should the respirations or cough reflex be allowed to become too depressed by medication. Carbon dioxide by inhalation is given in the treatment of atelectasis.

SUMMARY

The proper management of thoracic war injuries is a timely subject. The mortality of such injuries has always been high and many persons surviving such injuries have suffered prolonged chronic illness due to extrapulmonary or intrapulmonary complications. In order to decrease these hazards it is necessary that the medical officer called upon to treat such injuries understands the basic principles of the abnormal thoracic physiology resulting from chest wounds. The methods of treatment outlined in this paper are based upon these principles.

The first essential in the management of thoracic war injuries is the immediate care of such wounds. This requires the closure of sucking wounds, control of hemorrhage, and relief of a tension or pressure pneumothorax. This immediate treatment must be followed by early definitive treatment supervised by personnel qualified in thoracic surgery working in properly equipped medical installations where casualties with chest wounds are concentrated within a few hours after the injuries are incurred. All subsequent treatment must likewise be supervised by competent thoracic surgeons.

The treatment of shock in chest injuries requires the same close attention as in other injuries producing shock. It is imperative, however, that immediate attention must be given to correcting the abnormal thoracic physiology. The sources of hemorrhage and the methods of controlling such hemorrhage has been detailed. A wound producing an open pneumothorax or sucking wound of the thorax must be immediately closed. Concurrent and later therapy must conform to the principles outlined in correcting the abnormal physiology. A tension pneumothorax must be relieved. A simple method for accomplishing the decompression is by introducing a large bore needle into the corresponding pleural

cavity, preferably in the second intercostal space anteriorly 2 inches lateral to the sternal border. Care must be observed to prevent obstruction of the lumen of the needle. The recognition of massive pulmonary collapse and treatment directed toward re-expansion of the involved pulmonary tissue will greatly lessen the complications which frequently follow this condition. The phenomenon of bomb blast or "blast lung" has been discussed with a view of enabling its recognition and of preventing unnecessary surgical intervention. The management of cardiac concussion, cardiac wounds, and a rather detailed presentation of cardiac resuscitation have been described. The importance of an understanding of the fundamental principles underlying the proper treatment of acute empyema has been stressed. Foreign bodies in the pleural space should always be removed as early as possible. Many foreign bodies in the pulmonary parenchyma will require subsequent operations for their removal, and each case should be carefully investigated by employing all available aids in the localization of the foreign body before surgical exploration. The sulfonamide drugs should be employed in all thoracic injuries and operative procedures. The anesthetic agents employed in thoracic surgery and the utilization of these agents in war wounds of the chest have been discussed. The recognition of properly employed endotracheal anesthesia will, it is believed, be highly successful in the management of many chest wounds. Likewise the greater use of cyclopropane is considered advisable. Finally, modern thoracic surgery was born during World War I, and has grown to maturity during the past two decades. It is reasonable to predict that its proper employment will contribute to greater developments of this new field of surgery, that many lives will be saved, and that chronicity will be minimized.

WOUNDS OF WARFARE*

Frederick A. Coller, M.D., and Jack Matthews Farris, M.D.
Ann Arbor, Mich.

WOUNDS produced by the stone club of prehistoric man or by the tusk of the saber-toothed tiger or mammoth were probably the first pathologic conditions observed by man in which the etiology was known. It is almost unbelievable that we should know so little about them today. A thoughtful reading of the historical aspects of the treatment of wounds is obligatory to a proper understanding of the philosophy of the subject. Without this one cannot well evaluate the modern suggestions for the management of wounds. With every war there is a revival of interest in the methods of caring for wounds, since there is produced a laboratory for observation and experiment. Up to the time of Lister many worth-while suggestions based upon empirical observations were made and discarded. Infection in wounds was not a matter of paramount importance to the early writers on Surgery. Hippocrates, Celsus, Franco, and Paré did not emphasize its frequent or fatal occurrence. It is probable that in their day infection was neither inevitable nor serious.

Serious infection in wounds is first commonly mentioned in the surgical writings of the eighteenth century. It is significant that at this time hospitals had been established in which the wounded were congregated for treatment *en masse.* Accounts of hospital gangrene, erysipelas, and putrid infections then made their appearance in the surgical literature. While many surgeons made important observations on treatment, it remained for the founding of bacteriology by Pasteur and its application to surgery by Lister to bring some rationale to the treatment and prevention of infection in wounds. The students of Lister established the principle of antisepsis that acted potently upon the bacteria found in the air, on the patient, and in the exudates. Carbolic acid and its successors were the forces that were to abolish bacteria from wounds of accident or intention. Through the antiseptic to the aseptic era enormous progress was made and modern surgery originated. Pus remained an emblem of defeat, however, and it was washed, irrigated, drained, and neutralized by a great number of chemical agents. With the progress of civilian surgery, surgeons became more complacent and infection had apparently been conquered.

World War I shook us from our smug satisfaction by presenting to a generation of surgeons, who thought wound infection a condition of the Dark Ages, a clinic in which all wounds suppurated. Accepted techniques and chemicals were suddenly powerless. There were at first many attempts to find new and more powerful antiseptics. The failure of these methods led to a realization that wound repair like growth comes from within and that the surgeon can only

*From the Department of Surgery, University of Michigan, Ann Arbor.

aid nature to limit and to destroy infection. Without enumerating all the steps by which this change in viewpoint came about, one can state that at the end of the war it was the object of the surgeon to convert the wound produced by the missiles of warfare to a clean one. This was accomplished by removing foreign bodies and dirt of the battlefield along with devitalized tissue. This operation, carried out in the stage of contamination, was called débridement. The historical aspects of this operative procedure, originating with Baron Larrey, need not be elaborated here. It was finally realized that the state of the patient himself played an important part in the end result. It became apparent that lost blood must be replaced, shock must be overcome, and malnutrition must be corrected. Wounds already infected were treated in the later period of that war by several methods, all of which gave good results. The French employed a modification of Ollier's methods developed by him in the Franco-Prussian War. The principles of these methods included free drainage, thick absorbent covering, immobilization, and infrequent dressings. Carrell and Dakin's treatment, with frequent irrigation of a wound with hypochlorite solution combined with meticulous dressings, had many advocates. In the British Army the use of hypertonic salt or magnesium sulfate solutions was popular and efficacious. Free drainage and rigid fixation of the part were fundamental to all methods.

In the years that have intervened, surgery has made great progress in the scientific study of factors that influence the processes of repair. Much has been learned concerning the bacteriology of infections and the use of chemotherapeutic drugs. An appreciation of the inhibitory effects of malnutrition has resulted in new concepts concerning the role of vitamins and hypoproteinemia in wound healing. Dr. Winnett Orr improved the Ollier technique and applied it successfully to the treatment of osteomyelitis and infected wounds of bones and soft parts. This method was used with remarkable results by Trueta in the Spanish Civil War. All these advances in our knowledge are applicable to wounds produced by any means and will be briefly reviewed.

The capacity for regeneration and repair as related to wound healing involves certain fundamental principles. To speak of the wounds of warfare categorically and to consider them apart from the traumatic and surgical wounds of civilian life may lead to certain omissions in the consideration of the general features of wound healing.* The influence of selective, purposeful mechanical pressure on wound healing has been discussed by Blair.[3] He has emphasized that pressure limits the amount of plastic substance that pours into the wound, prevents stasis, controls oozing, and eliminates dead spaces. Twyman[4] has demonstrated that epithelium proliferates readily when subjected to pressure that restrains the growth of connective tissue. For a rise in temperature of 10° C. the rate of cicatrization may be increased twofold.[5, 6] Other factors include the influence of electricity, radiant energy, diet and metabolism, vitamins, hormones, and the sympathetic nervous system.

---

*Quantitative factors may vary with the size of the wound and with wounds of different individuals and different species. Other well-known qualitative factors exert a potent force on the rate of healing. The accelerated healing observed in younger individuals indicates that healing in the young is more rapid than in adults because fibroplasia begins earlier.[1, 2]

The divers factors influencing such basic phenomena as fibroplasia, inflammation, and regeneration deserve more careful consideration than, perhaps, the empirical use of certain therapeutic drugs. Likewise, the reparative processes which follow wounds of mechanical, chemical, electrical, or thermal agencies do not need individual consideration, since there is little difference in the injuries inflicted.

Variations in terrain may influence the bacteriologic flora of the soil, and the increased mobility of the front presents problems in transportation which may result in delay in treatment. The indiscriminate mass attacks directed against densely populated cities, coupled with the increased effectiveness of air forces, have often resulted in a multiplicity of wounds and numbers of wounded out of proportion to existing facilities for their care. The increasing range of artillery fire, combined with the mobility of the front and the omnipresent airplane in turn, tends to limit the type and the amount of operating permissible at the front. Notwithstanding these difficulties, the general features of wounds remain the same from the physiologic standpoint, and those of warfare do not differ in any basic respect from those of civilian life.

WOUND INFECTION

Approximately 75 to 80 per cent of all wounds in modern warfare occur as a result of low velocity projectiles from artillery fire.* The type of wound commonly received is lacerated and contused, usually contaminated by foreign bodies, and requires extensive débridement to facilitate its healing and to avoid systemic infection. Unfortunately, it is true that many wounds escape contamination at the time of infliction only to become grossly contaminated before definitive treatment is completed.

(a) *Bacteriology.* If one divides the organisms introduced into the wound at the time of infliction from the organisms introduced at some later date, the former may be referred to as primary infection and the latter as secondary infection. It is significant that the organisms found in a primary infection are relatively nonpathogenic and grow poorly in unaltered blood or tissues. They will multiply, however, and produce clinical signs of infection when there is devitalization of tissue and when the antitryptic power is lessened by the breakdown of leucocytes. This is especially true of the spore-bearing anaerobic bacilli associated with gas gangrene and tetanus. These organisms are capable of producing infection and toxemia only when there has been alteration of blood and tissues. The hemolytic streptococcus is rarely present at this stage. The source of the primary infection is usually from the soil, the skin, or the clothing. The missile itself is frequently sterile. In the soil, in the air, and on clothing most of the bacteria are relatively nonpathogenic as compared to the hemolytic streptococcus.

*The value of physical prophylaxis of wounds is apparent from the fact that cranial wounds have been reduced from an incidence of 15 to 3 per cent since the introduction of the steel helmet. It is significant that the great majority of wounds are caused by small irregular missiles of low velocity. Although the armor necessary to protect against high velocity bullets may weigh as much as 20 pounds, compressed fiber or bakelite panels (with the same tensile strength as aluminum and one-half the weight) will suffice for protection against shrapnel and trench-mortar splinters. It is logically assumed that many chest and abdominal wounds, which in the past have been caused by low velocity missiles, may be prevented by the use of some form of lightweight body armor.

Secondary infection is of greater clinical import, these infecting bacteria reaching the wound through other agencies. Hemolytic streptococci are usually spread from patient to patient by the personnel caring for the wounded. In the last war it was shown that at the casualty clearing station only 15 per cent of the wounds exhibited the presence of the hemolytic streptococcus, but after a week at a base hospital over 90 per cent of wounds were infected with this organism. Droplet infection from the nose and throat, infected dust, instrument, and bed linens are important contributing factors. It has been shown that if the floor is treated with crude liquid paraffin or with certain proprietary preparations, subsequent sweeping of the floor does not cause large numbers of streptococci to appear in the air from infected dust.[7] In pre-Listerian days the spread of *B. pyocyaneus* through a surgical war was well known, since its presence was revealed by the characteristic color. The spread of *B. pyocyaneus* from patient to patient is not usually a matter of great moment to the patient, since this organism is of low virulence, but it is of the utmost importance as an illustration of some of the failures in technique in the care of wounds.

(b) *Operative Technique.* The success or failure of any débridement depends on the persistence in the wound of nonviable tissue or gross foreign matter. Although as early as 1897, a German surgeon, P. L. Friedrich, published experimental work emphasizing the treatment of contused wounds as if they were neoplasms, the factor of vitality of tissues as the decisive element in infection has not been given its due importance.[8] In the Franco-Prussian War only 9 per cent of the wounds were caused by shellfire and approximately 90 per cent by bullets.[9] With the development of modern warfare, the ratio has been almost completely reversed. Approximately 75 to 80 per cent of all wounds in modern warfare occur as a result of low velocity projectiles and, therefore, require débridement.

The ideal for which one must strive is to make a clean wound out of a dirty one and above all else not to make it any dirtier. Without appearing didactic one may enumerate sound surgical principles which have stood the test of time. Excessive trauma and rough handling of tissue with improper instruments may only serve to increase the amount of devitalized tissue, thereby defeating the primary purpose of the débridement operation. Failure to obliterate dead spaces and the mass ligation of tissue likewise contribute to the incidence of infection rather than help to prevent it. The indiscriminate use of irritating chemicals in the wound should be vituperatively condemned as an agency capable of increasing the devitalization through coagulation of protein substances in the cells.

Suture materials should be chosen with care. The reiteration of the theme that one type of suture will persistently give good results in the hands of anyone is to be condemned. Rather more emphasis should be placed on the effects of trauma, tension, incomplete hemostasis, and a consideration of various pathologic conditions. Well-controlled experiments[10] emphasize, however, that all sutures are foreign bodies and as such should be used sparingly. Foreign bodies when implanted into tissue normally cause a reaction characterized by leucocytic infiltration, the accumulation of serum and fibrin, increased heat, and

even swelling. A foreign body reaction superimposed upon attempts at repair in a healing wound will delay the onset of fibroplasia, and infection will be more frequent. Theoretically, then the ideal suture is one that causes the least reaction in tissues, thus allowing the normal prompt initiation of fibroplasia. When healing is complete, the suture should either disappear from the tissues, or if nonabsorbable, its continued presence should not prove objectionable.

Many objections raised in the past in regard to catgut pertain primarily to its large size. If the smaller sizes of chromic catgut are used with interrupted sutures, many objections which in the past have been reiterated will no longer be tenable. In this connection it is well to point out that there appears to be little indication for the use of plain catgut in any situation. The intensity of the leucocytic reaction incited by its presence is roughly twice as great as in the instance of chromic catgut, and in certain instances its holding strength is negligible in three or four days. The difference in cellular reaction between the absorbable and nonabsorbable sutures may in part be attributed to the large caliber of catgut which was frequently used. It is obvious that no reason exists for the use of suture material with a tensile strength in excess of the holding power of the tissue itself.

There is no great difference in cellular reaction when silk, cotton, steel wire, or nylon is used. However, cotton appears to possess certain advantages. Cotton has a natural twist which is maintained after implantation in tissue, and, therefore, there is less of a tendency for granulation tissue to infiltrate the interstices of the individual fibers to serve as a possible nidus of infection or as a source of a draining sinus. In addition, cotton being a vegetable fiber is chiefly cellulose whereas silk is mainly protein. In general, proteins incite more reaction than nonprotein substances. From an economic standpoint cotton possesses other advantages: a mile of cotton costs about 50 cents, while a similar length of catgut would cost somewhere around $200! The threatened impending shortage of silk need cause little concern among the many proponents of nonabsorbable sutures inasmuch as cotton appears to fulfill the criteria for an all-purpose suture. It does not delay the onset of fibroplasia, and its continued presence in the wound is not objectionable. Even in the presence of grossly contaminated wounds, the development of a draining sinus or extrusion of the sutures is almost never seen.

Stainless steel wire appears to be a suture material which is tolerated extraordinarily well by tissues. It is practically impossible to attribute any type of quantitative reaction to its presence in either experimental or clinical studies. Since 1937 it has been used for suturing the fascial layers in approximately 95 per cent of several thousand laparotomies at the University of Michigan with excellent results. It has never been necessary to remove them from an infected wound, and the incidence of infection itself has been substantially lowered by its use. Similar experience is related by Jones of the Cleveland Clinic, who reports a diminution in the incidence of infection in combined abdominoperineal wounds from 28 to 2 per cent directly attributed to the use of stainless steel wire in the abdominal wound.[11] It is easily sterilized, resists deterioration, and should lend itself well to the requirements of military surgery.

There are certain instances, however, where the use of catgut will definitely lead to inferior results. Nonabsorbable sutures are an integral part of standard techniques of tendon suture which have resulted in substantial improvement in this phase of surgery, as noted by many surgeons. O'Shea's study of 870 cases of severed tendons has shown that the use of catgut was followed by suppuration in 15 per cent, whereas when silk was used, the incidence was reduced to 3 per cent.[12-15]

(c) *Skin of Patient.* The adequate preparation of the skin before beginning débridement is just as important as in an operation for appendicitis. Utilization of "skin technique" and isolation of the wound margins with drapes will result in a diminution in the introduction of secondary invaders into the wound. That the skin is a potent source of contamination is apparent from the experiments of Carraway.[16] In clean laparotomy wounds bacteriologic studies made on the knife blade employed in the initial skin incision yielded positive cultures in 20 per cent of the instances.

(d) *Hands of Personnel.* The benefits accruing from vigorous and methodical scrub scarcely need mention. This one procedure, along with the wearing of sterile gloves, has probably contributed more to improvement in wound healing than in any other single factor. Wherever it is possible, aseptic technique should be rigorously preserved. Even slight compromises in technique are certain to jeopardize results.

(e) *Air of the Operating Room.* Bacterial dissemination in the air of the operating room is influenced by a wide variety of factors. The whispering and talking of traffic and galleries increase the bacterial count tremendously and emphasize the need for the wearing of masks by all who enter the operating theater. The care of the floors and walls where a large number of patients are being treated is important to prevent the spread of infecting agents. The good results obtained by the sterilization of air either by formaldehyde (Gudin[17]) or ultraviolet light (Gardner and Hart[18]) illustrate the importance of keeping the bacterial count of the air of the operating room at minimal levels.

(f) *Nose and Throat of Personnel.* At one time Meleney found that 30 per cent of his operating team harbored hemolytic streptococci in their *noses.* This serves to illustrate the necessity for covering the nose as well as the mouth with some type of serviceable nonpermeable mask. Many masks in common use are notoriously ineffective in this regard, since they allow free permeation of bacteria through the interstices of the material. Epidemics of upper respiratory infection among the operating personnel will frequently result in an increase in the incidence of wound infection unless the strictest precautions are observed. Meleney has shown that from 35,000 to 60,000 bacteria may fall upon the operating field in one hour.[19]

MANAGEMENT OF THE WOUND

Where these principles are observed, excellent results will be obtained. Only the most enthusiastic of idealists would deny that the conditions of warfare will frequently preclude adherence to these well-founded fundamentals. However, when compromises in technique must be granted, it is important to recognize them as such and to plan accordingly in the management of the wound. Sur-

geons of evacuation hospitals soon become specialists in débridement, but their experience should not be obtained at the expense of the early wounded. Successful débridement will be accomplished only through a sound knowledge of anatomy and the general features of wound healing. It must include excision in mass of all torn, crushed, discolored and noncontractile muscle, along with loose bodies and devitalized bone. Primary closure of these wounds may be undertaken only exceptionally, and it is here that judgment and experience are of prime importance.

Ogilvie,[20] in an excellent discussion on the treatment of wounds, carefully divides the progress of wound infection into two stages: contamination and infection.

In the first stage, contamination, bacteria which have been carried in by the inflicting agent lie on its surface, in bits of dirt, clothing, fragments, or in blood clot. This is the stage in which the bacteria can be removed by thorough mechanical cleansing.

In the second stage, infection, the bacteria profiting by the culture medium available have multiplied and started to invade the host. For practical purposes the stage of contamination may be considered as lasting eight hours before it passes into that of infection. Methods of closure are governed by the age of the wound, an estimation of the degree of contamination, and the general facilities at hand.

(*a*) *Primary Closure.* The state of the patient's skin and clothes and the appearance of the wound will aid in an estimation of the probable degree of infection. Doubt as to the condition of the wound should always incline one to pessimism rather than to mistaken optimism. Primary closure may be undertaken only exceptionally when the skin edges come together without tension, when the wound is seen very early, and when there is opportunity for continuous and careful observation of the patient subsequently. In addition, the contamination should be minimal and facilities for adherence to the strictest operative asepsis should be at hand.

Recent observations in actual battle conditions are as follows:

"A large proportion of wounds have been operated upon in the forward area. The recognized débridement was carried out in as many early cases as possible. The wounds were saucerized, sulfanilamide was dusted on the surface, followed by a vaseline dressing or loose pack. *All these cases did extremely well.* Some wounds had been sutured, but with the exception of a very few cases, *were badly septic on arrival at the base*, with sutures cutting out and in pain from suppuration under tension."

The same remarks are applicable to amputation. Those with complete skin closure have seldom met with success. They likewise have arrived at the base hospitals with the sutures cutting out, the skin sloughing, and with pus in the deeper tissues. Amputation under battle conditions should be planned, if possible, to permit of reamputation at one of the sites of election. Whenever possible, flaps should be cut and allowed to fall over the end of the stump.

(*b*) *Delayed Closure.* A delayed type of primary closure may occasionally be utilized in the wound that has gone beyond the rather arbitrary eight- to

twelve-hour limit.[21-24] A simplified technique for carrying out this procedure in dirty wounds has been described in a previous publication.[25] The skin sutures are placed at the time of the débridement but are not tied, and a pack left in the wound for a twenty-four-hour period will set up an inflammatory reaction in the subcutaneous layers. Clinical experience indicates that this inflammatory reaction enhances the ability of the wound to deal with the subsequent development of infection. Little, if any, disadvantage results from leaving the skin unsutured for two or three days. If the wound remains comparatively sterile, delayed primary suture is a means of diminishing the period of hospitalization with reduction of disability.

Secondary suture may likewise be employed in certain selected cases. A septic wound of the soft tissues in the course of about fourteen days is usually relatively clean if proper treatment has been carried out. By this time necrotic tissue has separated, and the granulation tissue has assumed a healthy appearance. Information as to the bacteriology of the wound may be obtained by suitable laboratory procedures.

It is probably advantageous to clean carefully the wound with continuous wet dressings for two or three days before performing secondary closure.

It is becoming more and more evident that the best dressing for any raw surface is skin. Even though the new skin is merely a temporary covering to be later replaced with another type of graft for functional or cosmetic reasons, its early use may avoid weeks of pain along with disability from scar tissue contracture. The healing of extensive raw surfaces by secondary scar formation should be avoided wherever possible.

Padgett and Hood,[26] of the University of Kansas, have perfected a calibrated mechanical device for cutting large sheets of skin at virtually any predetermined level. Whereas the Thiersch graft as cut with the hand knife may vary from 0.010 inch to 0.018 inch, the dermatome graft of Padgett may be cut in any range of thickness from 0.008 to 0.024 inch. A full thickness skin graft in an adult varies in thickness from 0.032 to 0.040 inch. The "three-quarter" thickness graft is cut at a level 75 to 90 per cent of the thickness of the skin. The degree of contraction of the base of a wound is proportional to the thinness of the overlying graft. In some areas a thin graft may contract as much as 60 per cent. Many objections raised in the past to split-thickness grafts are invalidated when this thicker type of graft is employed as cut with the dermatome. The ease with which it may be used makes virtually anyone proficient in this particular phase of surgery.

ROLE OF SULFONAMIDES IN WOUND HEALING

It has been estimated (Colebrook) that streptococci are responsible for at least 70 per cent of all deaths subsequent to wound infection. Only 15 per cent of wounds culture streptococci within twelve hours, but at the end of a week of hospitalization the incidence increases to about 90 per cent. Droplet infection from the nose and throat, infected dust, instruments, and bed linens are important contributing factors. It seems, therefore, that if sulfanilamide were present in the circulating blood at the time the organism reaches the tissues, a systemic

infection might be prevented. There is reason to believe that the sulfonamide group of compounds have a high value in combating and preventing infection in wounds. Their systemic use after the wound is infected and after operation in the stage of contamination as a prophylactic measure is well established.

Sulfanilamide as a topical application for wounds was first used in the Spanish Civil War. The results of such treatment, however, were lost when Barcelona was captured with disorganization of the entire medical service. Reports from France reveal that sulfanilamide was used in the French Army, applied directly to wounds as a prophylactic measure. It has, of course, been used subsequently in both civilian and military surgery, with some difference in opinion as to its general effects. Where the number of wounded is out of proportion to the facilities at hand for their care, it has been shown through recent military experience that the local use of the sulfonamides may prevent the transition of the stage of contamination to that of infection. In such an instance débridement may be utilized after the eight- or twelve-hour arbitrary dead line rather commonly employed in the past.

Jensen and his associates[27, 28] were the first in this country to publish observations on the topical use of sulfanilamide in wounds. They demonstrated "that sulfanilamide is more effective when implanted locally than when given systemically in preventing wound infection. Local sulfanilamide will not prevent infections in the presence of massive doses of contaminating organisms, although it does appear to lessen the severity of these infections.

"Devitalized tissue will inhibit the activity of locally implanted sulfanilamide. Foreign matter will protect the contaminating organisms against sulfanilamide." Chemotherapy is no substitute for careful surgical débridement, immobilization of the part, and skillful general aftercare. More carefully controlled studies are necessary to the final evaluation of locally applied sulfa chemicals in lengthening the time element when débridement can be done in contaminated wounds. There is no substitute for meticulous operative treatment done at the earliest possible time. In both the immediate and postoperative care of the wounded man, it is well established that the general nutrition of the patient is extremely important. Shock, hemorrhage, dehydration, and starvation must be treated and overcome. Especially important is hypoproteinemia that may result from malnutrition, hemorrhage, or from a septic course with much exudation. Proper diet, transfusion, plasma, and amino acid mixtures must be used to correct this nutritional abnormality.

It has been shown that a proper vitamin intake is essential to orderly wound healing. Vitamin A is related to epithelial cell growth; vitamin B complex apparently influences proliferation of fibroblasts; vitamin C plays an important part in collagen formation and in fibroblastic growth. A food intake rich in these essentials is necessary for tissue repair.

Much remains to be learned from the observations and tests of experience, but we now face the care of those suffering tissue injury with more assurance. The scientific studies of the past two decades have given us a sound foundation on which to build new and better techniques.

HEALING OF WOUNDS*

Lieut. Col. Warner F. Bowers, M.C., U. S. Army

Wound healing is a process which intimately concerns every surgeon, but this fundamental subject has received only superficial consideration, for the most part, until very recently when the basic principles have begun to be more widely appreciated. This paper attempts to epitomize the known facts from various angles, basic and clinical.

BIOPHYSICS OF WOUND HEALING

As soon as a wound to tissue is sustained, serum and blood accumulate and coagulate in the wound space and to a lesser degree in the interstices between the surrounding uninjured cells. Into this damaged area, cellular elements of the blood, wandering tissue cells and new capillary loops are attracted. These capillary loops make up granulation tissue which pulls the wound edges together as the fibroblasts mature. This briefly is the entire process of normal healing and it is dependent on certain fundamental phenomena, namely: ameboid movement of cells, mitotic proliferation of cells and maturation of cells engaged in fusion of wound surfaces. Ameboid movement of cells is stimulated by the presence of blood, tissue fluids and a large number of other substances. Inadequacy of oxygen and nutritive substances in the relatively ischemic border of the wound may cause tissue hunger and anoxia followed by cell division and ameboid activity of fibroblasts and endothelial buds. Immediately after tissue injury the lytic phase of wound healing begins and here the dead tissue elements are removed by phagocytes. This also is called the lag phase because reparative processes do not begin until toward the end of the lytic phase. Phagocytosis is followed by an influx of wandering connective tissue cells and then proliferation of the invading fibroblasts begins. Now, two fundamental processes begin to operate. The stereotropic response of growing cells to surfaces causes the growing fibroblasts to elongate along the fibrils of the fibrin network in the coagulum, filling the wound space just as epithelial cells show ameboid movement along plane surfaces of granulation tissue and beneath crusts. This stereotropic response thus causes the fibroblasts to grow out and invade the wound space on the trellis of fibrin fibrils. A second factor which operates toward the same end is that of centrifugal force which directs growing cells away from their own kind and so into the plasma mass in the wound space. Endothelial buds also exhibit this phenomenon which may be an electrochemical mechanism; like cells with like surface charges tending to repel each other. Wounds become firm as the maturing fibroblasts contract and surface epithelialization progresses. The expected time of healing of any wound readily can be computed mathematically

using the Carrell-DuNouy[1] formula which is calculated on the basis of surface area. These computations also apply to the healing of granulating cavities such as those seen in empyema. I have previously shown this to be the case in some unpublished work quoted by Carlson.[2]

SYSTEMIC CONDITIONS INFLUENCING WOUND HEALING

1. Tissue age, whether adolescent, normal adult, senescent, or degenerated, influences the rate of wound healing not only because young tissues heal most readily but because old tissues are apt to show vascular changes which retard healing. 2. The state of hydration of the tissues as determined by water, electrolyte and protein balance in the blood exerts a profound effect on wound healing, and these factors will be discussed separately and in more detail later. 3. Normal nutritional balance is a somewhat vague term which probably covers the aggregate of many of the other factors which influence wound healing. 4. Vitamin balance will be discussed in detail later and will be found to be one of the most fundamental but least known influences on wound healing. 5. The general state of circulation and blood picture influence wound healing as they affect the interchange of cellular and ionizable elements between normal and damaged tissues.

LOCAL FACTORS INFLUENCING WOUND HEALING

1. There is a quantitative relationship between the amount of killed or damaged tissue in the wound and the time required for phagocytosis and repair. 2. Vascularity of the tissues involved is of prime importance in wound healing. Avascular tissues must depend on lymph spaces for interchange of nutritive and waste materials, and since most authorities deny that lymph flows, this interchange depends upon diffusion gradients for exchange of ionizable substances and ameboid motion for ingress of cells. 3. As a corollary to the preceding statement, the local blood supply to the wound must be intact, for no matter how vascular the tissue, if the blood supply is jeopardized by trauma, healing will be retarded in direct ratio. 4. The amount and character of the exudate in the wound space and in the tissues bordering on the wound determine the rate of healing in large measure. 5. The number and nature of the infectious organisms in the wound space and bordering tissues have a profound bearing on wound healing as infection throws an added burden on the reparative mechanism. 6. The number and type of foreign bodies which must be encapsulated or extruded from the wound influence the rapidity of wound healing.

RELATION OF TISSUE pH TO WOUND HEALING

Normal tissues preserve a neutral reaction by means of diffusion between the blood stream and local tissue spaces. Injured tissue accumulates acid metabolites and the breakdown of dead tissue also liberates split protein products which are acid in reaction. These factors influence the injured area and cause a shift in pH toward the acid side. Menkin[3] shows that neutrophilic leucocytes are attracted to slightly acid areas, and these cells therefore congregate in the injured area. If acidity exceeds the optimum point, the neutrophilic leucocytes are killed and macrophages are attracted. If the macrophages are able to phagocytose enough dead tissue to decrease the acidity, the inflammatory

reaction regresses; but, on the other hand, if the acidity increases, the macrophages also are killed and suppuration results. As the neutral stage is regained, such cells as the lymphocytes and plasma cells migrate to the site of reaction. From this discussion it seems that chemotaxis is largely responsible for the accumulation of the various cellular elements at the site of inflammatory reaction.

ROLE OF VITAMINS IN WOUND HEALING

Vitamin A deficiency causes such clinical manifestations as night blindness, photophobia, dry skin, dry conjunctivae, blepharitis, follicular hyperkeratosis, and numerous or severe infections. This latter may be of some importance in wound healing but such terms as "local tissue immunity" and "site of local lowered tissue resistance" usually are employed only to cover ignorance. About 35 to 50 per cent of people show deficiency in Vitamin A by the photometric test; however, this test is not generally accepted as accurate. About 12 per cent of individuals show clinical deficiency of vitamin A, as evidenced by one or more of the previously mentioned clinical manifestations.

Of the vitamin B complex, B_1 or thiamin chloride seems to be the only factor of importance in the healing process. B_1 seems to be identical with one of the components of the carboxylase enzyme system governing metabolism in nerve tissue. Therefore vitamin B_1 is of importance in the healing of injuries to nerve tissue.

Vitamin C (ascorbic or cevitamic acid) is the most essential vitamin in the healing process because intercellular substance in general and in the capillary bed in particular, as well as the collagen of all fibrous tissue, requires cevitamic acid for its production and maintenance. Lack of vitamin C causes hemorrhage into the wound space with a lag in healing and a tendency to wound disruption. Vitamin C deficiency in experimental animals has been shown to delay return of tensile strength in wounds. About 40 per cent of indigent clinic patients are deficient in vitamin C and all patients over seventy years of age show a relative deficiency. Patients placed on a strict ulcer diet become deficient in vitamin C within four days. These figures are arrived at by using the skin test or the capillary fragility test. Many superficial studies of wound dehiscence have been published and various factors have been blamed, but it seems reasonable and probable that vitamin C deficiency is the most universal and important factor. Vitamin C deficiency has many other interesting implications as has been emphasized recently by Levine,[4] who states that German soldiers receive 100 mg. of crystalline vitamin C daily.

Vitamin D is irradiated ergosterol which is related to cholesterol, one of the group of sterols which are of extreme importance in basic cell physiology because the sterols are responsible for the selective permeability of cell membranes. The presence of these sterols in the surface film enables the cell membrane to change its colloidal state from a water in oil to an oil in water emulsoid and, therefore, both oily and aqueous substances may be taken into the cell selectively.

Vitamin K, a water-soluble naphthohydroquinone, is responsible for maintaining the level of blood prothrombin. K is absorbed from the gastrointestinal tract only in the presence of bile so that in cases of biliary obstruction, K is not

absorbed, the prothrombin level drops and the patient tends to bleed. Vitamin K deficiency is of importance in wound healing only in patients having biliary obstruction.

The story of vitamins is not yet told but this seems to sum up our present knowledge of vitamins as they relate to wound healing.

RELATION OF STATE OF HYDRATION TO WOUND HEALING

Water is necessary to carry nutritive elements and waste products in solution and since these solutions must be isotonic with blood, relatively large quantities of fluid are essential. The many other implications of this important subject have been covered by the papers of Coller and Maddock.[5] Suffice it to say here that either too much or too little fluid retards wound healing. The state of hydration of the surgical patient may be gauged by: 1. The urinary output. 2. Specific gravity of the blood as measured by the falling drop method.[6] 3. The McClure-Aldrich salt edema test.[7] The surgical patient must have a daily urinary output of at least 600 c.c. and preferably 1,000 c.c. The falling drop test measures the concentration of the blood, and by the use of a simple chart blood protein levels may be quickly read off. The McClure-Aldrich salt edema test depends on absorption of skin wheals of normal saline solution, and the rapidity of absorption is an index of the tissue hunger for fluid and salt.

RELATION OF ELECTROLYTE BALANCE TO WOUND HEALING

Sodium chloride is the most important electrolyte and is almost entirely responsible for the osmotic pressure of intercellular fluid. Accumulation of salt in the tissues attracts fluid, edema develops, and edematous tissues do not heal properly because of altered pressure relationships and insufficient ingress and egress of materials. Decreased concentration of salt in the tissues causes a loss of fluid into the vessels with consequent tissue dehydration. Adequate fluid balance, therefore, depends on salt balance, and both are very important in wound healing.

RELATION OF LEVEL OF PROTEINEMIA TO WOUND HEALING

Protein is the most important colloid element of blood, and as the quantitative level of blood protein is decreased, the osmotic pressure and diffusion gradient are so altered that fluid tends to leave the vessels and accumulate in the tissue spaces. Blood protein levels of lower than 5 mg. per cent result in this type of edema. Deficiency of protein as well as edema retards wound healing. Ravdin[8] has shown that abdominal wound disruption developed in over 70 per cent of dogs operated upon in the presence of hypoproteinemia. There was little or no evidence of fibroplasia in these cases up to two weeks after operation. On the other hand, a high protein diet speeds up wound healing and almost eliminates the lag phase.

RELATION OF METABOLIC RATE TO WOUND HEALING

Theoretically, an increase in basal metabolic rate should speed the healing process, but such does not seem to be the case. Goiter incisions in patients with very high metabolic rates do not heal any more readily than other types of

incisions about the neck. Routine administration of thyroid extract postoperatively to speed wound healing and increase the circulatory rate to prevent thrombophlebitis has been advocated but has not proved to be of value.

RELATION OF LOCAL BLOOD FLOW TO WOUND HEALING

Local blood flow brings in most of the cellular elements which are so important in wound healing, brings in nutritive elements, and carries off metabolites. In addition, there is a very important mechanical factor to be considered. If a large vein is damaged, it should be ligated because the thin wall precludes suture, and since veins usually are multiple, sufficient venous channels will remain. If a large artery is damaged, it should be sutured if feasible but if this is impossible, a very different physiological problem arises. Blalock has shown that if a large artery is ligated, its accompanying vein also should be ligated. This procedure has the effect of causing blood to remain longer in the involved area and thus the injured tissues have more time to make use of it. If the artery alone is ligated, the venous channels of return overbalance the arterial supply and the area is drained of blood. Ischemic gangrene may be the result. This is a very difficult point to make, and while many surgeons advocate and teach it, few have the courage of their convictions. The rationale is clear and I have seen it work in practice.

EFFECTS OF TEMPERATURE ON WOUND HEALING

The application of heat to most potentially infected wounds by the use of hot packs, hot water bottles or light cradles is almost universal but may be very dangerous. There may be three serious disadvantages to the use of heat on wounds. 1. Heat may speed up local tissue metabolism to the point where the damaged vessels cannot adequately supply the increased demand for fuel and gangrene results. This is more frequent than is realized in such cases as diabetic infections which progress to gangrene. 2. Heat cannot be carried away because of damaged vessels so that a cumulative effect is present and causes increased tissue damage. 3. Heat augments capillary filtration and so increases local edema which may or may not be beneficial as will be discussed later. It is a safe rule never to use external heat of more than 100 degrees, and a thermometer always should be hung in the light cradle. Refrigeration in the presence of vascular damage probably is more rational than the use of heat. Refrigeration decreases metabolic needs so that a damaged circulation may be adequate. Fay has applied this principle to the treatment of carcinoma because malignant tissue has a higher metabolic rate than normal tissue, and refrigeration may cause death of tumor tissue before normal tissue is affected.

ROLE OF PRESSURE AND TISSUE TENSION IN WOUND HEALING

I previously have shown[9] that in a hollow viscus distention of the lumen or increase in the tissue tension will cut off blood flow sufficiently to cause inflammatory changes within the walls and this will progress to gangrene and perforation even in the complete absence of bacterial infection. Wound healing in other tissues is slowed by increased pressure or tissue tension because of reduction in blood flow or hindrance to physicochemical processes. Brooks[10]

showed that the period of viability of tissues rendered completely anemic by pressure is remarkably constant at 18 hours. The time element seems to be much more important than the degree of pressure because very low pressures may cause gangrene if applied constantly over a long period of time. Edema or external appliances may exert sufficient pressure to cause tissue damage and mild degrees of damage heal by fibrosis which, in such cases as Volkman's contracture, may lead to serious dysfunction.

IMMOBILIZATION AND ELEVATION IN THE TREATMENT OF WOUNDS

Immobilization is a well-established principle in the treatment of fractures, but its benefits in soft tissue wounds are not so generally appreciated. Complete immobilization in soft tissue injuries not only facilitates healing but also relieves pain, prevents deforming contractures and facilitates nursing care. Immobilization for soft tissue wounds was used extensively in the late Spanish War and has been exhaustively discussed by Trueta and others.

Elevation of the injured part makes use of the force of gravity to aid in return of blood and lymph from the site of injury and is an extremely important mechanical principle. The fundamental question as to whether the inflammatory reaction to healing and infection is the result of bacterial action or is a defense mechanism on the part of the host has never been satisfactorily answered. If the former, then treatment should combat the reaction, and if the latter, therapeutic measures should augment the reaction. Edema fluid is said to contain antibodies, and swelling may occlude tissue spaces and inhibit bacterial spread. On the other hand, edema increases pain, decreases circulation, slows healing, and may provide a fluid medium through which bacteria disseminate. Elevation of the affected part definitely reduces inflammatory edema and makes the patient more comfortable. Healing is facilitated but there are two dangers connected with the use of elevation. 1. Elevation of the lower extremity puts an extra load on the vascular system because blood does not flow up hill without work. Particularly in older patients the angle of circulatory efficiency must be watched closely. The toes of elevated extremities should be checked repeatedly for drop in temperature, and the vessels must be palpated for adequate circulation. I have seen a number of cases of gangrene develop from excessive elevation of the leg in young persons. 2. Elevation causes pus to settle by gravity and travel along fascial planes toward the trunk. I have seen several huge gravitational abscesses develop under casts applied with the leg in elevation where the abscess was some distance proximal to the original infection. The papers of Wangensteen[11] discuss the factors of immobilization and elevation in the treatment of wounds in considerable detail.

PRIMARY VS. DELAYED CLOSURE OF WOUNDS

The decision as to whether primary or delayed closure of a wound is to be employed depends on the time that has elapsed since the injury and also on the degree of obvious contamination. Primary closure in a clean wound is indicated up to 8 hours after injury, but recently I have seen wounds of much longer duration, involving tendon suture, primarily closed with good results by implanting

sulfanilamide powder at operation. Ordinarily, however, dirty wounds or clean wounds seen after 8 hours are treated by delayed closure. If the wound meets the criteria for primary closure, it should be flushed with large quantities of saline solution or washed repeatedly with soap and water. Bad habits are difficult to eradicate so that the instillation of so-called antiseptic solutions into wounds still is practiced widely. Closure should be accurate but without tension. Silk sutures may be used in clean cases, but catgut is safer because of the disagreeable sequelae if silk is used in the presence of infection. Catgut has a number of disadvantages, among which may be mentioned the fact that it is a foreign protein and occasions a certain amount of inflammatory reaction during its ultimate liquefaction and absorption. Certain patients absorb catgut very rapidly, and there is some question of allergy in these cases. In wounds which are doubtfully clean, it is possible to place adhesive tape close along the wound edges and then to suture the adhesive instead of the tissue. This procedure makes it a simple matter to open the incision if infection develops. If the wound does not meet the requirements for primary closure, it should be treated in one of the ways to be discussed later and then, when a smear from the granulating surface shows a bacterial count of less than 10 organisms per high power field, secondary closure may be done or the wound may be covered by a skin graft.

DÉBRIDEMENT OF WOUNDS

Contused and multiple lacerated wounds require careful excision of all obviously devitalized tissue because of the danger of infection, particularly by the anaerobic organisms of tetanus and gas gangrene if dead tissue remains to use up oxygen and act as a culture medium. A study of ballistics shows that for various sizes and velocities of projectiles, there are definite areas of tissue on all sides of the injury which subsequently will die as a result of the concussion. Therefore, it is important for the surgeon to know what type of projectile caused the injury in order to determine how much tissue to remove. Poor judgment in this matter may seriously affect subsequent healing.

ANTISEPTICS IN INFECTION AND WOUND HEALING

Many kinds of saprophytic bacteria and higher organisms live on the normal human skin, the number and kind depending on the environment and the degree of personal hygiene of the individual. A clean skin usually shows 12 staphylococci or diphtheroids per square centimeter. Other common organisms in addition to fungi are spore formers, the colon group, and Bacillus proteus. This indicates that all wounds are at least potentially contaminated but simple flushing of wounds with saline solution or soap and water usually suffices to remove these nonpathogenic organisms. However, from time immemorial men have searched for the magic colored solution which will kill bacteria *but not* harm tissues. Notwithstanding the expensive and varicolored solutions *on* the market today, such a desideratum has not yet been attained. The practice of pouring these solutions into defenseless wounds simply increases the tissue burden and should be discontinued. Novak[12] showed that all common alcoholic antiseptics kill 96 to 99 per cent of skin organisms, but 50 per cent alcohol plus 10 per cent acetone alone kills 97 per cent. It, therefore, seems irrational to pay

\$10 a gallon for certain commercial solutions. Novak made up a solution of 0.5 per cent cresol and 0.07 per cent bichloride of mercury in 50 per cent alcohol and 10 per cent acetone solution. This solution kills 100 per cent of diphtheroids, 99.6 per cent of staphylococci, costs but 60 cents a gallon, and has been successfully used clinically for at least three years at the University of Minnesota General Hospital. Novak solution has been used for skin preparation at the Station Hospital, Ft. Leonard Wood, Mo., since the hospital opened on May 3, 1941, with an extremely low incidence of wound infections.

TREATMENT OF INFECTED WOUNDS

The fact that such a large number of agents have been recommended for the treatment of infected wounds indicates that the ideal method has not been discovered. However, it is well to bear in mind the outstanding points in the use of these various substances.

Dakinization. Dakin's solution is an aqueous buffered solution of sodium hypochlorite which liberates chlorine. Chlorine has the effect of liquefying fibrin, dissolving dead tissue, killing bacteria, and, therefore, is beneficial in any infected wound. The solution has the disadvantages of rapid deterioration, short action, objectionable odor and requires an elaborate system of bottles and tubes for proper use. Dakin's solution dissolves the cornified layers of normal skin and, therefore, the area around the wound must be protected by vaseline gauze. The solution will sterilize a wound in 48 hours if correctly used and will transform pus into a transparent, mucinous substance with only a slight choline odor. Azochloramide is a more stable preparation which liberates chlorine over a longer period and consequently is less irritating to normal tissue. Dichloramine T is an oily preparation which disintegrates still more slowly. Dakin's solution was extensively used in the last World War, but it is predicted that it will be little used in the present war.

Maggot Treatment. Maggots were first introduced in the treatment of chronic osteomyelitis because it was observed that infested cases were found to be the cleanest. The application later was broadened to include all infected necrotic wounds. There are several ideas as to why the larvae are effective. 1. It has been suggested that the larvae actually eat the dead tissue and purulent exudate, thus mechanically cleaning up the wound. 2. It has been thought that larval excretions are responsible for the healing effect. 3. Dead larvae are thought to liberate a substance which is bactericidal. The use of live maggots is objectionable to patients because of the crawling of the maggots and from the esthetic viewpoint. Furthermore, the treatment is difficult to carry out because it is hard to obtain sterile maggots as needed. The problem has been approached by an effort to isolate the effective principle and by the application of macerated larvae in saline solution or ointment form.[13] Experimental evidence shows that these extracts and ointments definitely promote healing, and at present it does not seem necessary to use live maggots.

Cod Liver Oil. Cod liver oil is very valuable in the treatment of any infected wound and in prophylaxis in any open wound. The oil discourages bacterial growth and has a marked stimulating effect on granulation tissue. There

may be some truth in the claim that vitamin D is the effective agent because it is known that oxidized odorous oil is more efficacious than the highly purified product. Also, irradiation of other oils increases their healing properties. Cod liver oil may be used to fill cavities and soak dressings or may be used as a 30 to 50 per cent ointment in vaseline. Cod liver oil is of great usefulness in the treatment of infected wounds, empyema, chronic osteomyelitis, suppurative arthritis, burns, arteriosclerotic and diabetic gangrene.

Oxidizing Agents. Certain bacteria grow best in an atmosphere of lowered oxygen tension and grow well in symbiosis because one organism uses up oxygen, thus making an anaerobic medium for the other. A microaerophilic streptococcus is such an organism and causes a gangrenous spreading infection. One means of treatment is débridement followed by the application of a substance which breaks down to liberate oxygen. Meleny has popularized the use of zinc peroxide in such cases. This agent comes in powder form which is sterilized and then made into a thin paste with sterile water. The wound then is filled with paste-saturated sponges and a large airtight dressing is applied to inhibit evaporation and to prevent the rapid escape of oxygen.

Chlorophyll. Various vegetable substances recently have been advocated for use in treatment of infected wounds. Of these, chlorophyll[14] has received the widest trial. Chlorophyll inhibits bacterial growth apparently by preventing bacterial enzymic digestion of cell membranes. It is used in aqueous solution or in an oily base for suppositories or ointments. It may be given intravenously, by mouth, or it may be used as an irrigating fluid. Chlorophyll cleans up the wound and stimulates granulation tissue. It has had extensive clinical trial in such cases as wound infections, empyema, fistulas, deep abscesses, acute infections of the nose, throat and ear, male and female urinary tract infections. This substance should be cheap, easy to prepare, and almost universally present. It is interesting to speculate as to what role the vitamins in green vegetation may play in the healing effect of aqueous extracts.

Barberry. Folklore remedies which have stood the test of time deserve scientific investigation in order to isolate whatever specific principle may be present. One example of such work is the recent investigation of barberry by Dick.[15] Barberry has been widely used for centuries by aborigines as an infusion to cure surface infections and gonorrhea. Experimental work shows the effective agent to be berberine, which in 1 per cent solution kills erysipelas streptococci in 8 hours. Clinically, berberine has been successfully used in wound infections, decubitus, and varicose ulcers and mouth infections. It is dangerous when administered intravenously.

Pectin. Another folk remedy of proved worth is the apple diet for infantile diarrhea. The effective agent now is known to be pectin, which is found to be bacteriostatic in aqueous solution and stimulating to granulation tissue. Tompkins[16] and others have shown its worth in the treatment of various wound infections.

Silicon. The use of silicon in the treatment of wounds has a very interesting background. Mountain dwellers of Virginia have a tradition that eating sand will cause peptic ulcers to cease bleeding, and this led to an investigation of

silicon. It is known that silicon in the lung causes intense fibrosis of the pulmonary tissue, and Gardner has shown that this is in inverse ratio to the size of the particles of silicon. It seems established then that silicon promotes fibrosis, and the idea that silicon might cause wounds to fibrose was given a clinical trial with striking results. Silicon was ground to the finest powder and used in all types of wounds and ulcers with prompt healing. Silicon was given by mouth for bleeding ulcers and by cystoscope for bleeding tumors with equally good results. I saw these cases demonstrated in the Department of Surgery at the University of Cincinnati in 1934 and was deeply impressed but to my knowledge the work never was published. They were able to show elevation in the level of blood silicon by oral administration with favorable results in wound healing.

Specific Sera and Antitoxins. Gas gangrene, caused by Cl. welchii, is a frequent complication of war wounds because these anaerobic organisms are almost universally found in dirt. This complication is much dreaded because the gas generated by the organisms rapidly spreads along tissue planes and produces pressure necrosis of tissue. Manson has shown a 35 per cent incidence of Cl. welchii in indolent leg ulcers, and this has given undue alarm to many surgeons doing amputations in cases of diabetic or arteriosclerotic gangrene. In a published series, Kennedy and I[17] have shown that 38 per cent of milk cultures made at operation and at the site of amputation were positive for gas-forming organisms, but in no case was antigas serum given and in no case did gas gangrene develop. This illustrates our point that most of these gas formers are relatively nonpathogenic, and if amputation is done according to the criteria we laid down, favorable results will follow in a higher than usual per cent of cases. Formerly, gas gangrene was treated by massive doses of antitoxin, but its value is open to question, and the danger of foreign protein sensitization is great. Injection of oxygen into the tissues has been used with some success, but the most beneficial treatment seems to be with the x-ray or the local use of sulfanilamide. Tetanus is caused by Bacillus tetani, also a dirt organism, and is the cause of a high mortality rate. There is nothing new in the treatment of this disease, but it is suggested that zinc peroxide, x-ray therapy, and sulfonamide derivatives give enough promise to warrant investigative work. One answer to the problem may lie in the universal toxoid immunization to tetanus now employed by the Army, but some alarming anaphylactic reactions are being reported.

X-ray Therapy. Since the striking work of Kelley in the treatment of gas gangrene, peritonitis, and other severe infections by x-ray therapy, it has been suggested that it be used in the early treatment of war wounds. Keating and Davis[18] suggest that portable x-ray therapy units be placed with mobile surgical hospitals which already have power plants mounted on trucks. All dirty wounds would be treated within four hours after injury. This procedure is not to be recommended for three reasons: 1. Slight overdosage of x-ray therapy delays wound healing and may cause other well-known and more serious consequences. X-ray therapy given in all surgical hospitals would require many more trained radiologists than are available. 2. Not only is there danger of overdosage at one sitting but it is quite likely that in the rush of battle evacuation, records might not be completed so that patients might be treated twice. Such mistakes are not entirely beyond the bounds of possibility. 3. Local implantation of sulfanilamide

is so astonishingly successful in combating wound infection that it should not be discarded in favor of x-ray therapy, and most authorities state that the two modes of treatment should not be employed in the same case.

Sulfonamide Drugs. Sulfanilamide and its derivatives seem to act as bacteriostatics by virtue of their power to prevent bacterial cells from utilizing oxygen. Sulfapyridine was introduced to combat staphylococci, but it is relatively insoluble, gives a higher incidence of gastrointestinal upsets, and now is little used. Sulfathiazole is well tolerated by mouth, in solution in cod liver oil, or in ointment form. Excellent results have been reported from its use in carbuncles, operative wound infections, decubitus ulcers, corneal ulcers, chronic osteomyelitis, empyema and subcutaneous abscesses.[19] However, sulfathiazole is less soluble than the original sulfanilamide which is preferred for local implantation.

Local implantation of sulfanilamide crystals was first used in compound fractures by Jensen,[20] who reduced the previous incidence of severe infections from 25 per cent to nearly zero. Implantation gives a local concentration up to 800 mg. per cent as compared with 10 mg. per cent which is attained with difficulty by oral administration of the drug. This concentration is so great that all organisms are affected, regardless of whether or not sulfanilamide is specific for them. Saturated solutions of the drug may be used to irrigate infected cavities with excellent results. Local implantation of sulfanilamide around complicated gastrointestinal anastomoses[21] has greatly reduced the mortality, and its use free in the peritoneal cavity in cases of peritonitis has been beneficial.

It is to be remembered, however, that sulfanilamide is absorbed with great rapidity from the peritoneal cavity, its maximum blood level often being reached in 15 minutes after implantation. For this reason, the liver may be fatally damaged unless care is taken to use no more than 5 grams of the drug. I have seen three patients die of toxic hepatitis following the intraperitoneal introduction of 10 grams of the drug. It is suggested that every soldier be furnished with 5 gram ampoules of sulfanilamide with instructions to break one and pour the contents into a wound, whatever the site, as soon as incurred. The question of having the soldier begin oral administration of the drug or one of its derivatives also, immediately after injury, should receive earnest consideration.

SUMMARY

Biophysical, mechanical, chemical and bacterial factors are briefly considered as they relate to wound healing. The use of various and diverse substances in the treatment of infected wounds is discussed and numerous points are raised with the hope that additional investigative work will be stimulated.

WAR WOUNDS AND ANAEROBES

Lieut. Col. Roland I. Pritikin, M.C., 33rd Division, N.G.U.S.

(The writer states that the views expressed in this article are his own and that neither the Surgeon General nor the Medical Department of the Army is in anyway responsible)

HISTORY

Before we take up the study of anaerobes involved in war wounds let us view the history of the entire anaerobic realm.

In 1776 Spallanzani discovered that certain bacteria could live in an anaerobic environment. In 1861 Pasteur recognized the fact that certain organisms were able to exist and multiply in the absence of free oxygen.

The first of the pathogenic anaerobes to be discovered is the Leptothrix buccalis. Robin isolated and described it as early as 1847. In 1879 it was isolated by Trevesan. Frankel (1882), Michelson (1889), and Epstein (1900) observed leptothrix in connection with inflammations of the mouth and pharynx. Vignal and Arustamoff successfully isolated this organism.

Obermeier, engaged in the study of relapsing fever, isolated an organism which he called the spirillum of relapsing fever. This occurred in 1873. Little further work was done on this spirillum until thirty years later. From 1904 to 1908 various forms were discovered, among them the Spirocheta duttoni by Dutton and Todd in 1905; the Spirocheta dochii by Novy; the Spirocheta

Reprinted from The Military Surgeon 90: 164 (February), 1942.

carteri by Mackie; the Spirocheta vincenti by Blanchard. There are several types of relapsing fever and it is not yet known which types of spirochetes are responsible for the various types of the disease.

Schaudinn (1905) in his researches on Spirocheta pallidum very often found spirillum of very similar morphology. This spirillum is the Spirillum refringens, found in the mouth, tonsils, in ulcerating lesions, in smegma, and in venereal warts. Noguchi (1913), in cultivating various bacteria taken from lesions of the external genitals, discovered a new species, which he called Spironema phagedenae. Another similar anaerobic spirochete had been discovered in 1912 by King and Baeslake; they called it the Spironema hyos.

Framboesia tropica, a disease occurring in tropical and subtropical countries, was studied by Castellani (1905). He isolated from a large number of cases a spirochete which was named Spirocheta pertenue. It occurs in the cutaneous papules and ulcerations accompanying the disease. Von dem Borne repeated Castellani's investigations two years later and confirmed the facts stated by Castellani.

In the same year Schaudinn and Hoffmann carried on a series of investigations with syphilitic patients, examined primary syphilitic indurations and secondary enlarged lymph nodes, and discovered a spirochete which had not been described and which was found in infected syphilitic patients in a great proportion, and which was not found in uninfected patients.

Next to the Spirocheta pallidum comes the Clostridium tetani in interest from the standpoint of pathogenicity. Lockjaw had been known for many centuries, but it was not before 1883 that the causative agent of the disease was discovered. Carlo and Rattone in 1883 discovered it in the pus from a cutaneous lesion of a tetanus patient. They called it the bacillus of lockjaw. Nicolaier (1884) and Kitasato (1889), each carrying on investigations on tetanus, isolated and described a bacillus which is believed to be identical to the one described by Carlo and Rattone.

Van Ermergen (1896) investigated a portion of a pickled ham, the ingestion of which had caused disease of 34 persons, ten of them very seriously. He isolated an organism which he called the Bacillus botulinus. His work was confirmed by Romer (1900). In 1915 Nevin discovered another type of Bacillus botulinus, which he called Bacillus botulinus B.

Babes, Vincent, and Plaut are the chief workers on the disease known as Vincent's angina. In a throat smear of a patient suffering from Vincent's angina, Babes in 1889 isolated the Bacillus fusiformis.

A bacterium found in the stools of nursing children is the Bacillus bifidus, discovered by Tissier in 1900.

Less important are the following: The lymph node anaerobic bacillus, closely related to the bacteria group, also called the Corynebacterium, discovered by Torrey in 1916. The Bacillus egens, discovered by Stoddard in 1919. The multifermentans tenalbus, or Clostridium multifermentans, also discovered by Stoddard in 1919. The anaerobic pseudotetanus bacillus, or Clostridium tetanomorphum, discovered by MacIntosh and Fildes in 1917. Actinomyces necrophorus, discovered by Loffler in 1884, and the Treponema mucosum of Noguchi (1913).

A very extensive study was made of the anaerobic organisms associated with traumatic injuries during World War I. Most of the bacilli had been discovered long before the outbreak of the war, but it was during the war that we learned so much about them. The first of these organisms to be discovered was the Vibrion septique of Pasteur and Joubert (1877). B. welchii found in gas gangrene, usually in civilian cases, was first discovered by Welch and Nuttall (1892). This bacillus has also been called the gas bacillus, Bacillus perfringens, and Clostridium welchii. Another bacillus of this group is B. oedematiens, which infected a large number of wounds, according to the discoverers, Weinberg and Sequin (1915). In the same year Weinberg and Sequin isolated B. fallax, a slightly pathogenic anaerobe. The following year they discovered the B. histolyticus, an intensely proteolytic anaerobe found associated with the anaerobes in war wounds. In 1889, twelve years after Pasteur had discovered Vibrion septique, Cornevin, Arloing, and Thomas found a bacillus which they called the Bacillus chauvoei, the bacillus of symptomatic anthrax or blackleg.

Another organism that Weinberg and Sequin claim to have occurred frequently in war wounds is the B. sporogenes, discovered by Metchnikoff in 1908. In putrid wounds is occasionally found B. putrificus, discovered by Bienstock (1884). The B. sporogenes cadaveris of Klein is perhaps the same as B. putrificus. Tissier and Martally have found this organism present in putrid meat. The Bacillus oedematiens of Weinberg and Sequin is similar to, but not identical with, Bacillus oedematiens II, or bacillus of Novy, discovered by Novy in 1894.

TECHNIQUE OF ISOLATION

Anaerobic bacilli are comparatively difficult to isolate. It was not until World War I that efficient methods for the isolation of anaerobes were developed. The early workers usually were working with several organisms when they thought that they had a pure culture. MacIntosh and Fildes developed a good method for their isolation by using a technique which involved repeated plating of the anaerobic bacilli. Veillon's method was used by some workers. This consisted of inoculating agar shake tubes with varying dilutions of material. The tube is then filed through at the level of the colony, and the colony is then fished. The best method is Barber's method. (Developed by Barber in the laboratories of the Rockefeller Institute.)

In Barber's method a pipette is used to pipette out the colony. Barber claims that his method is not as time-consuming as the older methods, and permits the observer to make further observations on anaerobiosis, variability, motility, rate of growth, and behavior in a medium of small sowing exactly known than the older methods allowed.

An isolation chamber is used, 7 cm. long, 3.25 cm. broad, and 2 cm. high, which gives sufficient room and allows the use of a large cover glass, 60 by 35 mm. The cover glass must be heated very clean, because it may be used for growing colonies on it. It is carefully cleaned, smeared with vaseline, washed with hot water and alcohol, and wiped with a clean cloth. This leaves a very thin film on the glass. If sterilization is necessary, it should be done over a flame of low temperature so as not to melt the vaseline. The point of

the pipette should be made very fine, just large enough to permit the entrance of organisms. It should be about 5 micra in diameter.

With the aid of a microscope a small droplet is pipetted from a cover slip containing a thin film of the solution with the organism to be isolated. The droplets pipetted off should then be examined under oil immersion. This will insure the purity of the culture insofar as organisms visible to the oil-immersion lens are concerned. Invisible organisms cannot be guarded against.

The isolated organisms are then transferred to test tubes, or grown on cover glasses and then transferred. A fresh pipette is used for each organism, and the organisms are separately transferred to test tubes. Each new pipette has the tip sterilized by supplying same with a small amount of sterile broth before use. This aids also in washing the bacilli well into the tubes in the case where bacilli adhere to vaseline on the outside of the pipette. In washing the bacilli out, the technician must be careful not to blow any air into the culture. The pipette method is used upon seeding material isolated by the usual means. Air was removed by pumping in oxygen or by heating, the culture being covered by a layer of vaseline ⅕ to 2 cm. thick which prevents access of air. For growing spores in hanging drops, Barber used the following method: A shallow moist glass chamber, 45 mm. long, 25 mm. broad, and 2 mm. deep, is made. The isolated spores are arranged on a cover glass, 1.5 or 2 mm. apart, and sufficient media added. The undersurface of the cover glass, with the exception of the central portion containing the isolated spores, is then covered with a soft glucose agar culture of B. pyocyaneus, about 4 or 5 hours old. The area in the center may be surrounded by a thin paraffin wall to prevent spreading of the pyocyaneus. The bottom of the moist chamber is also supplied with a similar layer of pyocyaneus culture. Pyrogallic acid and KOH were used by Barber in connection with B. pyocyaneus, but they did not offer any advantage. Barber made sowings of the following bacilli: B. sporogenes, B. welchii, B. tetani, B. edematis, B. botulinus, B. of Ghon Sachs, B. aerofitidus, B. putrificus, B. bellonensis, B. tertius, B. fallax, B. edematiens, B. bifermentans, B. histolyticus, Vibrion septique.

Out of 400 one-cell sowings of bacilli, he succeeded in producing growth in 62, or 15.5 per cent.

He made 211 one-cell sowings, using all of the above, with the exception of welchii, edematis, aerofetidus and fallax and producing growth in 93, thus getting as a result 44.1 per cent. For the bacilli he used as media glucose broth, serum glucose broth, semisolid glucose agar, semisolid serum agar, firm glucose agar, firm Veillon agar, liver peptone agar, minced brain, liver peptone water under vaseline, liver peptone water in vacuum, milk and plain broth. For the spores he used in addition, egg cube and meat, but did not use liver peptone agar or minced brain. The bacilli, as a whole, grew best on the various glucose media, the spores on the semisolid glucose agar. Barber also found that spores remained viable after exposure for an hour or more, whereas bacilli were much more rapidly affected, depending on species. Barber found that B. sporogenes grows very rapidly, B. bellonensis very slowly.

In summarizing, Barber made the following statements: "(1) The pipette method has proved a feasible method of obtaining pure cultures of one-cell

anaerobes. (2) Both bacilli and spores may be used as seeding material, but spores give a much higher percentage of positives. Boiling alone affords a sufficient degree of anaerobiosis to the medium for initiating one-cell growth; and semisolid agar is the most convenient form of medium. Exposure to air during isolation apparently has no effect on the viability of spores of anaerobes, but young bacilli of some species suffer from a comparatively short exposure to free oxygen."

CULTURAL CHARACTERISTICS

The cultural characteristics of the anaerobic bacilli causing gas gangrene will be discussed. We may divide these up into two groups, saccharolytic and proteolytic, as follows: saccharolytic, B. welchii, Vibrion septique, B. oedematiens, B. fallax; proteolytic, B. sporogenes, B. histolyticus, B. putrificus.

B. welchii is a gram-positive, nonmotile organism. In older cultures it may become gram-negative. Its length is 4 to 8 micra, breadth 1 to 1.5 micra, straight and usually square. It may be coccus-shaped or rod-shaped, and has a capsule. It has no flagella, no spores, and is not very strictly anaerobic. The surface colonies on nutrient agar, serum agar, or glucose agar are circular in contour. Old colonies are 1 to 2 mm. in diameter. Young colonies, that is, colonies about 12 hours old are translucent. It ferments the common sugars, starch, and may ferment glycerin and inulin. It does not ferment mannite, dulcite, salicin. It grows rapidly on meat, with a formation of acid and gas. In milk we get what is known as stormy fermentation. Acid and gas are formed with remarkable rapidity in great quantities. No spores. In coagulated serum there is no change, no liquefaction, and spores are formed. In alkaline egg broth an opacity results. Gelatin is liquefied in 48 hours in an inoculated tube at 37 degrees Centigrade.

Vibrion septique is gram-positive, composed of slender rolls, strictly anaerobic, has spore formation, is motile, has no capsule. On meat we get a rancidity and gas. On milk, where it is usually found, it causes acidity, produces a little gas, and causes clotting. There is no liquefaction on coagulated serum. Alkaline egg broth growth results in opacity, but there is no clotting. It liquefies gelation. When grown on broth, a turbidity forms which settles to the bottom, leaving a clear supernatant fluid. It will ferment glucose, levulose, galactose, maltose, lactose, and salicin. It will not ferment glycerin, saccharose, inulin, mannite, and dulcite.

It may be differentiated from the B. chauvoei of Arloing, Cornevin, and Thomas by the fact that Vibrion septique will ferment salicin; B. chauvoei will not.

B. oedematiens is motile under strictly anaerobic conditions. It is a stout rod, 0.8 to 1 micron in length, which is somewhat wider than B. welchii. The rod is lightly curved. Autolysis sets in very early in B. oedematiens cultures. Strict anaerobic conditions for good growth are required. In meat we get gas; in milk, acid, and at the end of 4 or 5 days, a clot. Coagulated serum, no change. Broth, a flocculation and a semi-opaque cloud. Gelatin is liquefied. The production of acids is feeble in fermentations. It will ferment glucose, levulose, and maltose. It will not ferment glycerin, galactose, saccharose, lactose, mannite, dulcite, inulin, and salicin.

B. fallax is a motile, slender rod, 3 to 6 micra in length, has rounded ends, and is slightly curved. Gram-negative elements are frequent. When colonies are grown, those on the surface appear as round, crenated, slightly granular. The deep colonies are lenticular, irregular, or bean-shaped. It will not digest meat, but will form acid. In three to seven days a milk culture clots. With coagulated serum there is no liquefaction. The same is true of gelatin. All strains of B. fallax will ferment glucose, levulose, and maltose, but only a few strains will ferment galactose, saccharose, starch, inulin, and salicin.

B. sporogenes is ancillary to the condition of gas gangrene. It is actively motile, slender, forms spores, gram-negative in old cultures, gram-positive in young cultures, and is not absolutely anaerobic. The colonies have a wooly, tangled filament structure on the periphery, and have a hard center. The deep colonies are wooly. On meat there is a vigorous growth, with gas formation, an alkaline reaction, and a putrid odor. In milk a turbidity is formed which settles out, leaving a clear supernatant fluid, the reaction becoming alkaline. Coagulated serum is liquefied. In alkaline egg broth a flocculent precipitate falls to the bottom and is digested. Gelatin is liquefied. It will ferment only glucose, levulose, and maltose. Some of the other organisms ancillary to a condition of gas gangrene are: B. cochlearius, B. parasporogenes (McIntosh, 1917), B. tertius (Henry, 1917, Rodell as B. III of von Hibler as B. IX), B. tetanomorphus, B. aerofetidus, B. bifermentans, B. putrificus, B. butyricus, B. multifermentans tenalbus.

B. histolyticus is motile, rod-shaped, frequently arranged in pairs, is 3 to 5 micra in length and 0.5 to 0.84 broad. Cultural reactions are characteristic for the group. The surface colonies are delicate, flat, crenated, and have irregular edges. In agar the deep colonies are arborescent or corallike, with fine wooly ends to the branches. A white deposit of tyrosine follows digestion upon inoculation in meat. Coagulated serum is liquefied and gelatin is liquefied. Glucose, levulose, maltose-fermented.

B. putrificus is strongly proteolytic, gram-positive rod, oval spores, strictly terminal, giving drumstick appearance. Gelatin and serum are liquefied; milk is digested. It is found in gas gangrene and contributes to the putrid odor, but is in itself not pathogenic.

POWER OF RESISTANCE

In the classification of anaerobes we inquire as to their resistance to an oxygen environment. In viewing the bacterial realm, we notice that we have various groups as regards aerobism. To one of these groups atmospheric oxygen is a toxin. This group is the obligative anaerobe group. Barber's experiments showed that the presence of free oxygen stopped growth as follows: B. welchii, 23 minutes; B. tetani, 60 minutes; B. oedmatis, 10 minutes; B. botulinus, 6 minutes; B. sporogenes, 0 minutes; B. of Ghon Sachs, 6 minutes; B. aerofitidus, 10 minutes; B. putrificus, 1 minute; B. bellonensis, 6 minutes; B. tertius, 10 minutes; B. fallax, 6 minutes; B. oedematiens, 17 minutes; B. bifermentans, 6 minutes; B. histolyticus, 10 minutes.

No culture has ever been grown absolutely oxygen free; a little oxygen is always present. Anaerobes live symbiotically with aerobes to a great extent, and perhaps acquire oxygen in that fashion.

anaerobes. (2) Both bacilli and spores may be used as seeding material, but spores give a much higher percentage of positives. Boiling alone affords a sufficient degree of anaerobiosis to the medium for initiating one-cell growth; and semisolid agar is the most convenient form of medium. Exposure to air during isolation apparently has no effect on the viability of spores of anaerobes, but young bacilli of some species suffer from a comparatively short exposure to free oxygen."

CULTURAL CHARACTERISTICS

B. putrificus is strongly proteolytic, gram-positive rod, oval spores, strictly terminal, giving drumstick appearance. Gelatin and serum are liquefied; milk is digested. It is found in gas gangrene and contributes to the putrid odor, but is in itself not pathogenic.

POWER OF RESISTANCE

In the classification of anaerobes we inquire as to their resistance to an oxygen environment. In viewing the bacterial realm, we notice that we have various groups as regards aerobism. To one of these groups atmospheric oxygen is a toxin. This group is the obligative anaerobe group. Barber's experiments showed that the presence of free oxygen stopped growth as follows: B. welchii, 23 minutes; B. tetani, 60 minutes; B. oedmatis, 10 minutes; B. botulinus, 6 minutes; B. sporogenes, 0 minutes; B. of Ghon Sachs, 6 minutes; B. aerofitidus, 10 minutes; B. putrificus, 1 minute; B. bellonensis, 6 minutes; B. tertius, 10 minutes; B. fallax, 6 minutes; B. oedematiens, 17 minutes; B. bifermentans, 6 minutes; B. histolyticus, 10 minutes.

No culture has ever been grown absolutely oxygen free; a little oxygen is always present. Anaerobes live symbiotically with aerobes to a great extent, and perhaps acquire oxygen in that fashion.

During World War I it was forcibly called to the attention of the clinicians that the resistance of the bacteria to certain antiseptics did not have the same effect on the bacteria in the wound as it did in the laboratory.

Antiseptics of rapid action, which anaerobic bacteria are unable to resist, are Dakin's solution, eusol (hypochlorite solutions), and chloramine T. These antiseptics prevent further growth even in optimum media. With eusol the following figures will show result of action:

TIME EUSOL REMAINED IN WOUND	NUMBER OF COLONIES DEVELOPING	NUMBER OF BACTERIA PER C.C. OF FLUID IN WOUND, CALCULATED
5 minutes	2	200,000
20 minutes	50	5,000,000
30 minutes	40	4,000,000
60 minutes	25	2,500,000

TIME CHLORAMINE T IN WOUND	NUMBER OF COLONIES DEVELOPING ON PLATES
10 minutes	No growth after 24 hours Innumerable colonies after 4 days
20 minutes	Innumerable colonies after 4 days
30 minutes	Innumerable colonies after 48 hours
60 minutes	Innumerable colonies after 48 hours

The antiseptics used above are very destructive to anaerobes in the laboratory but their potency is dissipated in some way in the wound perhaps by contact with the walls of the wound, its discharges, or both of these factors. By experiments carried on in vitro it was discovered that the bactericidal efficacy of antiseptics is lessened in the presence of serum, and that leucocytes have a quenching effect upon antiseptic agents. The values for the concentrations of various drugs to inhibit completely the growth of B. sporogenes are as follows: Iodine 1:500; chloramine T 1:50; carbolic acid 1:200; mercuric chloride 1:2,000; crystal violet in 6,400. For B. welchii the values are as follows: Iodine 1:500; eusol 1:4; chloramine T 1:60; carbolic acid 1:200; mercuric chloride 1:2,000; malachite green 1:200; flavine 1:16,000; crystal violet 1:1,000. Dyestuffs in general exert an inhibitory effect on the bacteria. The bactericidal dyes lose a great deal of their potency by combining with the fabrics used for bandaging.

Anaerobes, and especially their spores, are comparatively resistant to desiccation. Light is a strong bactericidal agent, but in the case of the anaerobes, a completely anaerobic environment will interfere with the bactericidal action of light. Hydrogen peroxide is a strong bactericidal agent.

A hypertonic salt solution is an indirect bactericidal agent; it produces an accumulation of leucocytes. Electric light, x-rays, and radium light have an inhibitory effect on anaerobic growth. Electrical currents applied to a solution containing anaerobes will act as a bactericidal agent. Heat will kill anaerobes.

CHANNEL OF INFECTION—MOST COMMON SOURCE

The point of infection is the wound. Of the various types some are more liable to anaerobic infection than others. The more irregular and lacerated wounds become more highly infected. In the case of a wound caused by a shell particle acute infection follows for two reasons: The shell particle makes a rougher wound than the high-powered bullet, and the shell bursting on percussion with the ground carries with it as it enters the wound portions of soil,

which in highly fertilized districts may be heavily charged with anaerobes. Infection may take on various phases. We may get a localized anaerobic infection in the wound, slowly spreading anaerobic infection in the wounds; gas gangrene of the "group" type when a single muscle or group of muscles is attacked; gas gangrene of the massive type when a whole segment of a limb is involved; or the fulminating type.

Infection is aided by the following factors: Retention of extravasated blood; interference with the local circulation; the presence of masses of devitalizing tissues; extensive fractures and comminution of long bones; retention of wound secretions by dressing, pastes, or packings. The wound, if it has the shape of a cavity with a small surface opening, is ideal for anaerobic growth. Delay in the mechanical cleansing of a wound leads to acute infection, as does also the retention of foreign bodies.

PATHOGENICITY

In a wound a myriad of factors enter which determine whether an anaerobic infection will be apparent within an hour, or whether several days will elapse before distinctive features appear. An infection usually takes the following course: The wound has a brownish discharge, composed of broken down blood clots; it is foul smelling and gives off gas. The odor depends on the infecting organism and the stage of the wound. At the very beginning a characteristic smell is absent, but later it becomes foul and acrid. A serous infiltration occurs throughout the intermuscular septa and connective tissue. The accumulation of the fluid causes a swelling which takes on the appearance of a purplish ring around the wound. The muscle is at first not infected; when infection sets in, we have the condition of gas gangrene. The muscle tissue is invaded by the organisms and is gradually digested. If the blood supply is left intact, we are able to see the actual course of infection. The muscle becomes black, friable, and diffluent. Then we get several color zones, first red, then yellow. Contractility is lost and the muscle undergoes changes in coloring, beginning with red and changing to greenish yellow and then to black.

In another type the blood supply is cut off. The muscle changes color from purplish red to a greenish black diffluent mass. Gas forms first as bubbles between the muscle fibers, afterwards entering the areolar tissues. The gas has a deleterious effect, since it produces pressure in the fascial sheath and constricts the blood vessels. Interference with the blood supply is very favorable to infection, because neither the first nor second line of defense is given free play.

Toxin Production.—B. welchii produces a true exotoxin. An antitoxin was first developed by Klose (1916), which was not, however, as effective as Bergston's. Since B. welchii is the chief organism involved in gas gangrene, an antitoxin injection will remove the organism causing the most trouble, and will leave the minor gas gangrene organisms alone, among them the Vibrion septique and B. oedematiens, which come next on the list from the point of view of infection. B. welchii was isolated by Weinberg and Sequin in 72 to 80 per cent of the cases of gas gangrene studied by them during the war.* Pathogenicity and hemolytic power vary greatly with the different strains of B.

*World War I.

welchii. In fatal cases death usually results from a B. welchii septicemia. Spores are never formed in the animal body.

Vibrion septique has a very powerful toxin. It is a soluble toxin. A specific antitoxin has been developed.

B. oedematiens is, in general, pathogenic, although two nonvirulent strains have been isolated by Weinberg and Sequin. The lesion caused by B. oedematiens is characterized by a whitish, gelatinous exudate and absence of gas. B. oedematiens forms a soluble toxin, but does not cause the acute infection that Vibrion septique does.

B. fallax is very slightly pathogenic.

B. sporogenes was found in 27 per cent of the cases examined by Weinberg and Sequin; it is usually responsible for the foul odor in wounds. This organism is, however, not very pathogenic and produces a weak toxin.

B. histolyticus is intensely hemolytic and produces large lesions, but is nontoxic, and does not produce acute infections.

B. putrificus is actively proteolytic, produces foul odor and putridity in wounds, and is nonpathogenic. The condition of the wound under treatment may become better or worse. If better it heals; the pus is drained and granulation sets in. If the wound becomes worse, the gas gangrene condition rapidly encompasses more area, and we get a condition which demands amputation.

The infection, although primarily caused by anaerobic bacilli, is usually found to contain aerobes, usually streptococcus and staphylococcus. The anaerobes grow better under an environment containing aerobes. Thus to remove the aerobes, which are aiding in causing a media favorable to anaerobes, we inject some staphylococcus vaccine, or a vaccine made from M. tetragenus and streptococcus. The vaccine usually improves the wound. Vaccine gave good results in cases where a condition ensued in which there was a pyrexia, a cessation of the healing process, and an unhealthy appearance in the wounds. In the treatment we must be careful of our use of antiseptic: a very weak solution of chloramine T, for example, will have a stimulating effect upon the organisms.

DISSEMINATION WITHIN THE BODY OF THE HOST

In the case of gas gangrene, the condition is such that dissemination of the infective material to even a comparatively small extent is fatal. The treatment of a wound is determined by the danger of dissemination to a very great extent. If we have the wound in a limb, the limb must be amputated if the infection cannot be controlled. We give our antiseptics with the view of preventing spread of infection. Thus, when a patient is brought into the hospital, the wound is immediately washed with hypochlorite solution, and we apply eusol, Dakin's solution, or chloramine T. Hypochlorite solution is the most effective means for putting an initial stop to dissemination.

Slough-covered wounds are given frequent washings with a 0.5 per cent salt solution, which causes a liberation of a tryptic ferment upon the disintegration of the leucocytes in pus. An exudation of lymph also ensues. I will give a brief summary of a few cases showing dissemination of the disease. (Great Britain Medical Research Council Report 57: 122-150, 1920.)

I. Bullet entered right thigh, gluteal muscles affected by gas gangrene, no healing, general condition worse—amputation.

II. Gangrene in muscle of leg. Dissemination stopped by hypochlorite applications. Connective tissue repair.

III. Wounded. Was lying on the field for three days before he was picked up. He was very weak from loss of blood, and an infection spread in his leg. He was taken to the base hospital. Wound was treated with Dakin's solution, and every attempt was made to stop spread of infection. Infection continued spreading so that leg was amputated above the knee.

IV. He was wounded in the forearm. Incisions were made for gas gangrene. Infection was counteracted. Granulation tissue repair. Muscle was not as efficient as formerly after wound was healed.

V. Wound in right scapula. Incisions made on surface with extra precautions. Easily repaired. This type of wound offers comparatively little trouble.

VI. Wounded in leg. Muscle became gangrenous and was excised. Rapid recovery followed, although leg was not as efficient as formerly.

VII. Infection in gluteal muscles. Incisions were made into muscle, but did not aid in stopping spread of infection. Muscles excised. Fever followed, and large pieces of necrosed bone were removed from the neighborhood of the sacroiliac joint, which greatly improved the drainage of the deeper portion of the wound. The wound progressed wonderfully quickly, granulations springing up from the bottom and filling the cavity, the epithelium also spreading in from the edges. When later the concentration of material became great and contraction followed, but was not rapid enough, and epithelium stopped spreading, some 45 Steele's grafts taken from the patient's thigh were applied to the granulating surface, no special arrangement being adopted. A second skin grafting operation two months later when the scar tissue was very pronounced, and the granulations in consequence very bloodless, was an almost complete failure. However, under massage to loosen the scar tissue, and to promote circulation, healing progressed slowly and patient was discharged.

VIII. Bullet going through and through, leaves clean wound, very easily healed.

IX. Femur fractured. Drainage incisions made to curb infection. Infection stopped. Operation, binding bone with metallic thread. Operation for removal of metallic thread. Wound heals.

X. Infection attacks to the extent of septicemia, in very weak patient. Death.

XI. Pus from wounds in head drained. This condition is very dangerous due to proximity to the brain.

XII. Repeated amputations. Pleurisy set in. Death due to either septic thrombosis of the vena cava or septic thrombosis of the inferior or common iliac vein.

XIII. Wound healing. Severe secondary hemorrhage, wound opened, but bleeding point could not be found due to infiltration of blood and inflammatory exudation. Amputation found necessary and performed.

In general, we may say this about dissemination. An infection is started and we have an inflammation. Then there is a leucocytic infiltration. Necrosis sets in, muscle and bone tissue are destroyed, there is a lymphocytic infiltration, and a putrefied mass is formed in the wound. The wound has a tendency to close on the surface, leaving a putrid proliferative mass. A flesh wound on the abdomen, if severe enough, may gain entrance into the abdominal cavity. A case of gangrene in the abdominal region is rare, due to the fact that abdominal flesh wounds are easily treated. Dissemination of infection of a wound of this kind into the abdominal cavity is usually fatal.

Thrombosis, embolism, septicemia often result in cases of gas gangrene, the latter being fatal, the former two leading to a critical condition.

Various complications may arise. In gas gangrene septicemia a high temperature is reached (102 to 103 degrees Fahrenheit) and death follows. Very rarely we may get a gas gangrene pyemia. There is an invasion into the blood stream, secondary deposits of gas gangrene bacilli in various parts of the body when the tissues have suffered some slight damage, as from the introduction of a hypodermic injection, or an infusion of saline, or they may develop in tissues subjected to prolonged pressure as in the buttock, when the patient lies in bed tilted on one hip. The prognosis is extremely bad.

CLINICAL SIGNIFICANCE

A. *Diagnosis of the Disease From a Clinician's Standpoint*

1. *The physical standpoint:* The physical signs differ according to the type of the disease present. A localized anaerobic infection is distinguished by a foul-smelling discharge, mixed with bubbles of gas. If the disease is more extensive, swelling is noted, and upon percussion of the swollen area a tympanitic sound is heard.

By noting the type of wound, we are able to tell whether an anaerobic infection will soon be in evidence. Wounds with imperfect drainage, extensive devitalization, and death of tissue with extravasation of blood, will result in gas gangrene cases. Imperfect drainage is typical in cases where a projectile made a small point of entrance, entered deeply, and was retained. The general condition of the wounded man is also important. Infection develops much more readily in fatigued troops than in fresh troops. An irregular projectile forms a more irregular wound, and may carry bits of clothing, and thus increase the chances of infection. An area with a diminished blood supply precludes active intervention by the protective mechanisms of the body. When a wound becomes infected, it is an anaerobic infection up to the time the muscle is attacked, then it becomes gas gangrene. The muscle becomes black, friable, and diffluent, and the line of invasion is seen. In others we see red and yellow zones or bands. In some our chief symptom is a loss of contractility. The diagnostic features of gas gangrene are pain, crepitation, resonance on percussion, and what is more important, severe constitutional symptoms.

The disease may be one of several types. In the first type we have a localized anaerobic infection. In the second type we have slow spreading. In the third, swelling, and a tympanitic condition and crepitation may be detected. These symptoms become more marked as the disease continues, the skin develops large irregular fibrillae, with blood-stained serous fluid. There is a mottling of purple patches, becoming greenish yellow. The muscle becomes dry, brown, pultaceous, and finally black with a slimy surface. This third type is called the group type. The fourth is the massive type. Here the blood supply is cut off, constitutional symptoms, such as vomiting, rise in temperature, and a rapid pulse are noted. There is a rapid appearance of signs of decomposition. The fifth type is the fulminating type. Severe pain, extensive swelling of the affected part, rapid spread of the disease, and severe constitutional features are the symptoms.

2. *Symptoms:* In the early stages pain is very marked; the unusual amount of pain depends upon the increasing pressure within the wound. When the

infection becomes established, pain increases. There is a feeling of numbness in the superficial parts of the limb. The patient looks distressed and ill. Lips acquire a cyanotic color, the pulse rate is rapid, and the temperature rises 3 to 4 degrees Fahrenheit. There is continuous vomiting. If the disease becomes more rapid, becomes running and uncontrollable, there is more frequent vomiting, the extremities become cold and blue, the temperature falls. The mind, however, remains acute even to the end; in the terminal stages some degree of general icterus may be present. Death comes with dramatic suddenness; the specific cause is still unknown. Pulmonary embolism is never found in autopsy.

B. Laboratory Standpoint

The primary infection is largely made up of fecal material bacteria. B. welchii and associated anaerobes in symbiosis with aerobes, chiefly streptococcus and staphylococcus. After the healing process had begun and granulation tissue formed, no B. welchii were found upon laboratory examination. In recrudescence of bacterial infections after operations, the chief anaerobe to be found was B. sporogenes, always in company with streptococci and staphylococci. As soon as a case was brought into the hospital and physical diagnosis was made, samples of pus were collected and films and cultures were made. The specific organisms causing the infection are thus noted. Weinberg and Sequin give the following figures: B. welchii were found in 72-80 per cent of cases; Vibrion septique in 12 per cent of cases; B. oedematiens in 34 per cent of cases; B. sporogenes in 27 per cent of cases.

NEWER CONCEPTS IN THE TREATMENT OF BURNS*

WITH SUGGESTIONS FOR THE MANAGEMENT OF WARTIME THERMAL INJURIES

LIEUT. THEODORE A. FOX, M.C., U.S.N.R.

IN 1925, when the tannic acid treatment of burns was introduced a remarkable step forward was made in reducing the morbidity and mortality of thermal injuries.

It was soon discovered that tanning (with the later modification of applying silver nitrate to the area) relieved pain by protecting exposed nerve endings and stopped the escape of precious body fluids by forming a damming eschar over the raw area. Both were important factors in reducing shock. However, the method had two marked disadvantages.

In the first place, it was necessary to scrub the patient thoroughly before applying the tannic acid spray, for every effort had to be made to cleanse and "sterilize" the skin before applying, because tannic acid is not bactericidal. Infection and associated toxemia, once started beneath the tough protecting but masking eschar, would often be the cause of the patient's death. This dire complication is usually due to contamination of the raw surfaces before the tanning takes place and the eschar forms. The burned area is sterile for some time after the injury, since bacteria are killed by the same physical cause that kills cells and tissues. Toxemia is the second most important complication as a cause of death from burns; shock is first.

Secondly, when the epithelization occurred under the tough, inflexible eschar, the cells of epithelium that grow into the burned area from the unburned margins were not "normal" in that they, too, had been "tanned." The connective tissue beneath, instead of being elastic, forms tough, contracted bands under the deformed epithelium. This grave aftermath, usually of third-degree burns, frequently causes more concern than the original injury, especially if the face, neck, hands, or flexor surfaces of the extremities are involved. The patient recovers from the burn but is frequently left a deformed, crippled monster. Infection further increases the scarring, even though sulfon-chemotherapy has reduced the morbidity. The patient faces months of painful and expensive plastic surgery in order to return to a semblance of normality.

Not only is tannic acid (even with silver nitrate) nongermicidal, but it has the added disadvantage of being extremely unstable, necessitating fresh solutions whenever needed. Such an eschar is thick and likely to crack, and if the surface to be tanned is already infected, it will not "take."

*Reprinted from the U. S. Nav. Med. Bull. 40: 557 (July), 1942.

It was plainly seen after years of experience with this treatment that for the reasons discussed, the tannic acid method could be improved upon. What other methods could be used to give an antiseptic, analgesic eschar that would provide a dam for escape of tissue fluids, stimulate normal epithelization, and form a nondisfiguring scar?

Aniline dyes had been used in connection with burns for years; singly they did not seem to have the proper qualities to displace tanning.

In 1933 Aldrich[1, 2] happened upon the ideal combination of these dyes. He showed by culturing burns that they were sterile (due to thermal injury of the skin) up to eighteen hours after the injury occurred. If the patient showed no signs of toxemia after this, the wound remained relatively sterile. Up to the seventy-second hour a mixed type of infection could be cultured from the wound surface; and after that period, pure cultures of beta and gamma hemolytic streptococci could be demonstrated in a toxic patient. Aldrich felt that the infection was the cause of this early toxemia, rather than the previously suggested split proteins, and he was able to prove his thesis experimentally, not only by surface culture of the burn, but from blood cultures as well; he also showed that only infected cases became toxic. This led him to search for an eschar-forming dye that was noninjurious to the tissues, yet strongly germicidal. He found that gentian violet was effective against the gram-negative organisms. But it was not until he mixed crystal violet and neutral acriflavine (acriviolet) and brilliant green that he was able to kill the gram-positive organisms as well as the gram-negative, yet not injure tissues. Not only did these dyes in combination (1:1,000 solution) kill all germs; they formed a tough, purple-brown, supple eschar to seal the area, and provided excellent analgesia as well.

If a local area becomes infected in spite of the triple-dye treatment, it is not masked until late in the course of this complication, as it is in the tannic acid method. By daily observation a softened, moist area can readily be detected and by simply trimming it out and respraying the denuded area, one can quickly end this complication.

The three-dye mixture consists of 1 per cent aqueous solution of crystal violet (gentian violet also is used) and brilliant green, and a 0.1 per cent solution of neutral acriflavine. This mixture is quite stable and can be prepared and stored for a long time without losing its efficiency. The crystal violet is specific for gram-positive organisms and has a definite analgesic action in that it coagulates with plasma proteins to form the eschar protection for the exposed nerve endings. The neutral acriflavine and the brilliant green dyes have special germicidal action against gram-negative organisms. In dilution of 1:1,000 the mixture has a phenol coefficient for many of the pyogenic organisms. It is nontoxic to normal tissues, although it stains skin, mucous membrane, and granulation tissue (in fact, everything it comes in contact with) a purple-brown color.

Although dyes are messy to handle, this is insignificant in view of the facts that the morbidity and mortality from burns and the incidence of scar deformity have been markedly reduced with this treatment. Aldrich himself states that he does not "wish to give the impression that by merely spraying

with this dye there will be no mortality. The use of the triple dye makes treatment easier," but other aspects of the treatment, i.e., treatment of the patient, in general, cannot be neglected. He further adds that "it is not the final answer to all problems presented by a burn patient," even though the method is applicable as well to third-degree burns. Contrary to popular opinion, if no infection remains in these carbonized areas, the islands of epithelium that are spared (usually around hair follicles) are enough to grow and spread. Some mild contracture of scar and an occasional infection occurs with this method. "If a new substance is found, it will have all the properties of the triple-dye method and yet be an improvement." In other words, this new substance would have to lessen still further the possibilities of infection and scarring.

This "new substance" was introduced by Pickrell[20] in August, 1941, and is one of the amazing group of sulfon drugs, sulfadiazine (2-sulfanilamido-pyrimidine). In this author's introductory series of cases it was found to be much superior to methods previously used for treating burns.

It is a nontoxic, extremely bactericidal, analgesic substance that forms a tough, thin, pliable, and transparent eschar. No contractures resulted in any of Pickrell's cases, even when used around the eyes. It makes the patient so comfortable that 100 of the 115 cases treated were able to leave the hospital on the day of admission and be observed as out-patients. Like the triple dye method, no traumatizing scrubbing of the burned area is necessary. As the eschar is translucent, the granulization and healing can be observed directly; and it is so elastic that motion can be started immediately without cracking or disturbing the eschar in any way. None of the 115 cases developed any infection while the eschar remained in place.

The solution used is one of 3 per cent sulfadiazine in 8 per cent triethanolamine. It has a pH of 8.7; it is clear and has a faint yellow color owing to the oxidation of the sulfadiazine. This, although it does not materially affect the efficacy of the drug, may be prevented by storing it in dark glass bottles. It is odorless, has a bitter taste, and does not stain skin or clothing. It penetrates tissues and can be detected in the blood within several hours after being sprayed on a burned surface. After the eschar forms, the blood level approaches a minimum and remains level. Normal tissue is unaffected by the drug. The triethanolamine is nontoxic, as demonstrated in laboratory animals. If the blood level of sulfadiazine is kept below 15 mg. per cent (20 mg. per cent is the maximum for safety), it can cause no kidney damage. Temporary psychotic episodes and blood dyscrasias are rare with sulfadiazine, although blood counts, urinalyses, and sulfadiazine blood levels, taken at frequent intervals, are necessary to discover such rare eventualities. Other toxic manifestations as drug fever, drug rash, cyanosis, and jaundice seen in the sulfon drugs are extremely infrequent but should be watched for. However, in Pickrell's series only one case showed drug toxicity (kidney damage), even though sulfadiazine was administered orally to some patients as well as being used to treat the burn.

The treatment of burns is divided into two parts: (a) Treatment of shock (primary, secondary, or tertiary). (b) Treatment of the burn itself.

Treatment of shock should be undertaken *at once.* The most critical period for a burn case is eight to twelve hours after the injury has occurred. If the

patient has had a relatively severe burn and is not in shock, treat him as if he were. The treatment of the burn should not be begun until the shock therapy is well under way and the patient has a normal temperature, relatively normal blood pressure, a good pulse and respiratory rate, and his skin is warm and dry. Continue shock therapy while treating the burn. Wrap the patient in sterile sheets to protect the burn and *treat the shock*.

Primary shock is that stage that comes on immediately after the injury and is similar in every respect to surgical and traumatic shock. The contributory causes are: (a) The general withdrawal of blood plasma into the tissues and loss of plasma from the burned surfaces. (b) Severe pain from the exposed nerve endings.

Plenty of morphine should be given. Grain ⅓ to ½ can be administered with impunity and repeated every four hours, or as often as necessary to keep the patient comfortable. Pain itself is an excellent antidote for an overdose of this narcotic. So keep the patient free from pain.

Apply external heat in the form of heated blankets or a heat cradle. Hot-water bottles, electric pads, or anything available should be used to keep the patient warm.

Elman,[8] Black,[4] and others have definitely shown that the volume of blood during this stage is depleted by loss of plasma through the capillaries and larger vessels, and from the burned surfaces.

The administration of plasma at this time is to be strongly advised. If possible, plasma should be given to *all* severe burn cases. If this is not available, whole blood may be used, although this adds erythrocytes to an already too viscous blood. Parenteral fluids are contraindicated, for they further dilute the blood proteins and only temporarily stay in the peripheral circulation.

Rhoads[22] and his co-workers, Ivory,[16] and others, have shown that the use of adrenal cortical extract (eschatin, cortin) decreases capillary permeability and helps maintain the plasma level in the blood, thus reducing the incidence of secondary shock in severe burns.

Stimulants, such as ephedrine sulfate (grain ⅜), adrenaline (minims v-x), or other pressor substances; caffeine sodium benzoate (grains 7.5), strychnine sulfate (grain $\frac{1}{20}$), coramine (1 c.c.), metrazol (1 c.c.), may be administered parenterally if indicated. However, the above treatment should make their use unnecessary, except as a heroic measure.

The patient's head should be kept low (Trendelenburg position) to increase and maintain cerebral circulation. Due to the anoxia as a result of diminished blood volume and poor peripheral circulation, as evidenced by the high blood viscosity and low arterial blood pressure, it is recommended that oxygen be administered throughout the entire shock therapy by means of a Boothby mask. Poor oxygenation of the tissues is the prime factor in causing parenchymatous damage.

Secondary shock occurs from ten to twenty hours after the injury, but it may be delayed as much as two or three days, and is the so-called histamine shock of Cannon (absorption of tissue breakdown substances). The author believes it is merely a more extreme form of primary shock and should not occur if the patient is properly treated. It is due to increased hemoconcentration and can be treated with plasma transfusion and prevented by the use of

adrenal cortical hormone. During this stage the viscosity of the blood, which normally is 2.4 (taking water as 1.0), increases to 4.0 and 5.0.

Third type of shock is relatively uncommon and, if present, makes the prognosis very grave indeed. It is a prolongation of the second phase, with a blood viscosity so great (6.0 to 7.0) that the patient's own cells act as thrombi and emboli to cause cerebral, liver, and kidney damage (anoxia). This stage of shock is hard to treat, for fluids injected into the venous side of the circulation cannot be pumped out to thin the capillary blood. Prevention is the best treatment for this stage. Administration of plasma via the sternal marrow is the treatment of choice in this stage of shock (Tochantin).

Burns are classified as first degree (stage or erythema), second degree (erythema plus bullae formation), and third degree (stage of carbonization; erythema with bullae are also present).

In discussing the treatment of the burn itself, the general details will be taken up before going into the specific methods for the triple dye and the sulfadiazine-triethanolamine techniques.

In general, the following procedures are followed in the order in which they appear:

(a) Wrap the patient in sterile sheets and proceed to the operating room.

(b) Treat the shock; do not proceed until you feel reasonably assured that the patient is out of shock, and is being treated for shock during the burn treatment (see above).

(c) Don mask and cap. All observers, assistants, and nurses do the same. Remember outside contamination (especially droplet contamination from the noses and throats of spectators, etc.) causes infection of burns.

(d) Scrub in the usual manner; don gown and gloves (all assistants do the same).

(e) The burned areas are gently and carefully débrided of all dead tissues and bullae. The area is not cleansed or scrubbed in any way unless to remove, gently, previously applied grease or oil. Antiseptics are not applied to traumatize further the tissues.

(f) The dye or sulfadiazine solution is sprayed on the débrided area with an atomizer, as outlined below.

(g) If delayed blisters appear twenty-four to seventy-two hours or more later, the above procedure is repeated.

The triple-dye method is as follows:

(a) Follow the foregoing outline in preparing the patient. *Treat shock!*

(b) The dye solution (1 per cent aqueous solution of crystal violet and brilliant green and 0.1 per cent solution of neutral acriflavine) is sprayed on the burned areas every hour for eight hours. An eschar forms at the end of the first or second spraying, but is not complete until the end of eight hours.

(c) Keep a heat cradle (not over 90°) over the patient.

(d) Observe the eschar daily for soft, moist spots.

(e) Excise soft, moist (infected) areas, gently sop up secretions with a sterile sponge, then respray as above.

(f) Continue daily observations until epithelization is complete or the granulation tissue is built up enough to take a graft.

(g) In case of massive infections (seen where burns occur around body orifices and are continuously being contaminated), the eschar may be removed and the raw surface treated with saline spreads until clean and then resprayed.

(h) No dressings of any kind are applied.

(i) The eschar comes off in about one to three weeks with the surface beneath more or less normal skin. Rarely and only where the burn is third degree is a skin graft needed.

The sulfadiazine-triethanolamine method is as follows:

(a) Follow the same general outline for preparing the patient (see above). *Treat shock!*

(b) Spray the burned area with the solution every hour for the first twenty-four hours. A heat cradle at 90° should be used.

(c) Spray every two hours the second day.

(d) Spray every three hours the third day.

(e) Spray every four hours the fourth day. By this time a thin translucent eschar has formed that is soft and pliable.

(f) Encourage active motion; if the burn is not too extensive, allow the patient up and about. If the burn is less than 20 per cent of the body surface, discharge from the hospital. Motion prevents contractures.

(g) In about ten days the eschar begins to loosen from the epithelium beneath. Applications of the mixture or saline compresses speed the separation. In third-degree burns, allow the eschar to remain in place for three weeks. This type may need grafting. This is done after saline spreads have been applied for several days. Observing the burn through the translucent eschar makes the rare infection easy to detect. If present, soak off the eschar and respray.

(h) Ambulatory patients, i.e., those treated and sent home within twenty-four to forty-eight hours, are sprayed frequently during their stay in the hospital, and the burns are covered with sterile vaseline gauze or an ointment made up of 5 per cent sulfadiazine and 8 per cent triethanolamine. In these cases no eschar forms, so they are seen every twenty-four to forty-eight hours and the burns are resprayed and redressed with the vaseline gauze or the ointment. This is repeated until the burn has healed.

During wartime the treatment of burns presents several added problems. First, they are usually complicated with other injuries, such as fractures and soft tissue wounds. Secondly, the problem of sepsis is a greater one, because of the great amount of contamination and the inability to give the wounds and burns the immediate care needed to prevent infection. Koch believes that a wound or burn is contaminated and, therefore, potentially septic two hours after injury, provided no treatment is given the patient in that time. In the author's experience, six to eight hours are the upper limits. However, since the advent of the sulfon drugs and the "plaster-cast-let-alone" treatment, the latter being revived during the Spanish Civil War, it is possible to treat even these potentially infected wounds as "clean." Since the introduction of the sulfadiazine-triethanolamine treatment, this problem should be further simplified.

The spore-forming organisms are all too frequent contaminants of wounds in wartime; the administration of prophylactic doses of combined tetanus gas bacillus antitoxin is obligatory. Then again, as the eschar seals the burn from the outside air, a treated burn is an excellent place for the growth of these anaerobic organisms. In civilian practice some surgeons routinely give at least the tetanus antitoxin (3,000 units) to all their burn cases.

In reviewing the literature extant on the treatment of burns since the start of the present war, it is readily seen that no standardization of treatment has been devised. It is the author's impression that the greatest difficulty with this problem lies in the failure to set up a definite standard simple plan for first-aid and hospital treatment based on one or the other of the specific methods described in this paper. There are too many diversified forms of treatment, depending on the type of burn, its location, whether or not it is complicated by a wound, etc. There can be only one method for routine, standard treatment.

All the British authorities have agreed upon the necessity of treating the shock. They have reduced the mortality tremendously by using heat cradles, plenty of morphine, routine administration of adrenal cortical extract (2 c.c. per dose) in liberal amounts, and, best of all, the use of plasma. Primary shock from burns is not seen often in wartime Britain, but 80 per cent of deaths from this injury are due to secondary shock.

If the patient has a hemoglobin of over 100, it is obligatory to give him plasma and keep giving it until the hemoglobin readings reach more normal figures. Pseudopolycythemia is a good index to the increased viscosity of the blood—and taking a hemoglobin and/or red blood count are easy, quick ways of determining the concentration of blood.

In severely wounded cases British surgeons find it advisable to administer oxygen routinely by means of the K. L. B. mask (Boothby type). The Royal Navy, which has had this type of mask available for use, has found it invaluable in saving lives, especially in cases that are complicated by "blast lung."

Hot coffee (6 ounces) by rectum or by mouth has been a successful adjunct in treating the shock cases. It is an excellent stimulant and helps keep the patient warm. The latter factor is stressed, and a large percentage of injured men that were successfully kept warm at Dunkirk, lived, in spite of the lack of much else in the way of treatment. Any means available was used. Immersion in the sea seemed to help preserve body heat, for none of the burn cases rescued from the Channel were in shock.

As for the first-aid treatment there are as many methods as there are medical officers in the British Army and Navy. Tannic acid jelly seems to be the most generally used, since all tanks, gun turrets, etc., are equipped with tubes of this material. However, gentian violet, picric acid, acriflavine, paraffin, gentian violet and merthiolate, amertan jelly, tannafax, and tannax all have their advocates.

The tannic acid jelly is the favorite for first-aid applications; and when a burn case is first seen, the routine consists of plenty of morphine, keeping the patient warm, liberally spreading tannic acid jelly upon the undisturbed burn (no first-aid station débridement), and applying two or three layers of gauze over it and holding them in place by a bandage. This is left *in situ* until the patient reaches the hospital. Of course, his other wounds are treated, splints are applied, etc., at same time the burn receives attention, placing the jelly into wound surfaces if necessary.

The patients mentioned above who were immersed in sea water for long periods had a very low incidence of infection. Wakeley[24] favors the use of gentian violet in first-aid treatment over the tannic acid jelly because of its greater germicidal action, and for this reason even places this material into compound fractures.

After the patient gets to the hospital, he is assigned to a special ward for burn cases and taken to a special operating room. Due to the high incidence of crossed infections, burns are treated and bedded in "clean" operating rooms and wards.

If much dirt, grease, fuel oil, and dead tissue are present after the shock has been treated, the burn is cleansed and débrided under aseptic conditions,

the patient being anesthetized with either intravenous pentothal sodium or evipal (evipan). No untoward effects were encountered from these anesthetics. Little gas oxygen anesthesia is used and chloroform and ether are never employed.

The débridement consists of first shaving the hair and removing the fingernails and toenails, if necessary, around the injured parts which are then gently cleansed with ether soap. Cotton pledgets and soft friction are used. The wound is then rinsed; or if deep, irrigated with saline solution. The burned area is then dried with a hair drier.

The triple-dye method is used rather extensively in most British military hospitals. The incidence of infection and toxemia has been dramatically reduced by this method. The tannic acid-silver nitrate method is still used. However, where deformity is feared (i.e., in burns of the neck, face, flexor surfaces, or the hands), this treatment is avoided. The eschar of the triple-dye method, when used on the localities mentioned, is removed as soon as granulation tissue is favorable for skin grafting. This prevents deformity. Wakeley[24] uses a combined aniline dye (gentian violet) tannic acid treatment. He applies the dye first for its germicidal effect and then tans the area by the usual method.

Splints and casts are used by many surgeons to put the part to rest, but are not applied until all swelling has subsided. Heat cradles are kept over the patient at all times. Limbs are elevated to promote venous drainage and keep down swelling.

Saline immersion baths are used by some men for treating burns, especially third-degree burns and burns of the hands and flexor surfaces. Saline packs are used upon the face. This method also helps separate the eschar.

Mathews[18] uses the "tulle gras" method of treatment. This dressing is made up of close-mesh gauze and is cut into suitable squares, impregnated with soft paraffin (98 parts), balsam of Peru (1 part), and olive oil (1 part). These squares are packed in a covered metal container, each separated by white paper to facilitate removal, then the above paraffin mixture (250 Gm. for a container 5 inches square and 2 inches deep) is poured into the tray and is sterilized for an hour at 150° and the container is sealed. A local anesthetic (1 per cent decicain or 0.1 per cent percaine) may be added. This is applied to all raw surfaces and left *in situ* as long as the paraffin base lasts, and should be removed by saline immersions of the part. Some authors have used this method on hand and face burns. Gauze dressings saturated in saline are placed over the "tulle gras."

Cod-liver oil and cod-liver oil ointments are rather extensively used in Britain, especially for burns of the face and hands. German army doctors have been using this method; they use tannic acid for other burns.

Bunyan uses the "bag method" in treating his hospitalized burn cases. This consists of primary irrigation and cleansing with 10 per cent electrolytic hypochlorite solution at 100° with the patient under an anesthetic. Coated silk watertight envelopes are then placed on the limb over the burned area. No other covering is used. The envelope is so rigged and is sealed at each end that hypochlorite solution can be run through it, irrigating the wound. This is done two or three times daily.

Hudson[15] modified this method of Bunyan's by using impregnated silk as an occlusive dressing (where the bag cannot be used). If a large area of the

body is burned, he uses a large envelope that includes the entire body, then applies irrigations of hypochlorite. He also advocates the use of sulfathiazole cream in infected burns.

Extensive and third-degree burns are also treated by a large number of men by the saline-immersion method, 0.9 per cent saline at body temperature, which is thermostatically controlled. Some apply "tulle gras" after the immersions until grafting can be done.

Gas warfare has not been used to any great extent during the present war, and it is beyond the scope of the paper to discuss in detail the treatment of such burns. However, after specific decontamination, they are treated by the usual methods.

Chemotherapy is extensively used as an adjunct in treating burns. Sulfanilamide seems to be the drug of choice. Sulfapyridine is used only if pneumonia complicates the picture (this is not infrequent in severe burns), because of its "toxic reactions," such as nausea, vomiting, etc. Sulfathiazole is prescribed as well as the sulfanilamide, but not as extensively. Sulfadiazine was not mentioned by any of the authors. Powdered sulfon drugs are not used on burns, although they are put into wounds. As previously stated, Hudson[15] uses a sulfathiazole cream and Robson[24] uses a glycerin sulfonamide paste ("euglamide") in infected burns.

Plaster casts are used in deep burns or where the burns are complicated by other injuries. Casts are not applied until edema subsides. Then the limb is wrapped in sterile sheet-wadding and the part is encased in plaster in the position of function. They are not removed until healing has taken place, even though they become foul-smelling. This is the lesson learned from the recent Spanish Civil War. Apparently a bacteriophage is formed that inhibits bacterial growth in the patient's infected tissues, finally eliminating the infection. Little or nothing is mentioned, in any of the papers reviewed, about the routine administration of tetanus or gas bacillus antitoxins, nor is the incidence of these complications discussed.

In conclusion, the author can only urge that a definite, simple standard routine treatment for burns be adopted by the United States armed forces. In his estimation the sulfadiazine-triethanolamine solution is the treatment of choice. As was indicated, it can be used as an ointment in first aid and as a solution in the hospital treatment; it is stable, nontoxic, nonstaining, and highly bactericidal. The drugs can be placed into soft tissues and compound fractures or other wounds so that complicated burns need not have separate forms of treatment. It can be safely used on the face, neck, hands, and extensor surfaces with little fear of contractile scar deformity, even in third-degree burns. In short, it has all the advantages and none of the disadvantages of all the other types of treatment.

The standard routine treatment suggested is as follows:

FIRST-AID TREATMENT

(a) *Keep patient warm* by any means possible; blankets, coats, hot coffee, hot water bottles, etc. Place the patient out of the weather.

(b) *Relieve pain* by giving adequate doses of morphine, grain 1/3 to 1/2, every half hour if necessary.

(c) *Prevent loss of plasma* and plasma proteins by administering adequate amounts of adrenal cortical hormone (2 c.c. dose) parenterally. Plasma infusions should be started.

(d) *Apply sulfadiazine (5 per cent)—triethanolamine (8 per cent)—stearin ointment* ("lubricating jelly" should be used as a base to make a water-soluble ointment) to the otherwise undisturbed burned areas. No débridement is done. Apply a sterile dressing to protect the burned area.

NOTE.—In the alternate method the triple-dye ointment made up of an aqueous solution of 2 per cent crystal violet and brilliant green and a 0.2 per cent acriflavine in a "lubricating jelly" base should be used for the first-aid treatment instead of the sulfadiazine-triethanolamine ointment.

(e) *Remove the patient to a hospital* as soon as possible.

HOSPITAL TREATMENT

(a) Wrap the patient in a sterile sheet.

(b) Begin antishock therapy.

1. Place the patient in Trendelenburg position.
2. Apply heat cradle (90°).
3. Plasma should be given; adrenal cortical extract should be routine.
4. Give more morphine if indicated.
5. Oxygen should be routinely administered by means of a Boothby mask.

(c) Give the tetanus-gas bacillus antitoxin. (Is the patient sensitive to horse serum?)

(d) Operator and assistants prepare themselves for a sterile operation.

(e) The patient is draped.

(f) If burn and other injuries are extensive and dirty, requiring cleansing as well as débridement or other surgical procedures, intravenous sodium pentothal should be administered.

(g) Débridement and *careful, gentle* cleansing is performed. Wash and irrigate with sterile saline. Dry with hair dryer.

(h) A solution of 3 per cent sulfadiazine and 8 per cent triethanolamine is sprayed on the burns.

(i) The patient is placed in bed. Shock therapy is continued (plasma and cortate are administered) until blood shows normal viscosity. (Check hemoglobin and red blood cells.) A heat cradle is kept over the patient. *Be careful;* shock may be delayed up to ten and twenty hours after the initial burn.

(j) The burn is sprayed hourly the first day; every two hours the second day; every three hours the third day; and every four hours the fourth day. By this time the eschar is complete.

NOTE: If the sulfadiazine-triethanolamine solution is not available then the triple-dye aqueous solution (1 per cent crystal violet and brilliant green and 0.1 per cent acriflavine) should be used to spray the burn. The spraying is done every hour for eight hours.

(k) Check blood and urine daily for sulfadiazine levels and crystals, respectively. Do not allow the former to go above 15 mg. per cent.

(l) Observe the eschar daily. It is translucent and the tissues beneath are in clear view. If the burned surface beneath appears infected, remove the eschar with saline soaks, apply sterile saline spreads for a few days and then respray.

(m) When the eschar begins to loosen (about tenth day), warm saline immersions can be used to help loosen it. Do not remove a third-degree burn eschar under two weeks. It is best to leave it in situ for three weeks.

(n) Encourage motion. Get the patient up and about as soon as possible; on the day of admission, if feasible. The soft eschar does not interfere with motion.

(o) If large denuded areas of granulation tissue remain after the eschar falls off, apply saline spreads for a few days and perform skin graft as soon as possible to prevent disfiguring scars.

The triple-dye method can be substituted for the sulfadiazine-triethanolamine ointment and solution. It is almost as efficient, but is messy and has more tendency to cause disfiguring scars, although these are not as severe as in the tannic acid treatment. The dye method has an advantage in that it is more economical. Sulfadiazine is still a rather expensive drug; however, the added cost is justified by the lowered incidence of morbidity, mortality, and deformities. The tannic acid treatment for burns should be discarded, for with the newer treatments this method has outlasted its usefulness.

MILITARY DISCIPLINE*

A Problem in Readjustment

Lieut. Col. Patrick S. Madigan, M.C., U. S. Army, and
Lieut. Col. Malcolm J. Farrell, M.C., U. S. Army

SINCE the birth of our nation it has been necessary to expand rapidly our military forces to meet the major military conflicts in which our country finds itself involved. Once again we are faced with the problem of raising a large military force, consistent with military efficiency and the urgency of the situation, in as short a time as possible.

In this swift expansion many persons must make a rapid readjustment; their being uprooted from civil life and placed in a military environment may, in many cases, result in neuropsychiatric difficulties. This change may alter not only a person's hopes for the future but also his manner of living substantially. Two changes are especially difficult for him: first, the loss of his individuality; and, second, the loss of personal liberty. He soon comes to feel that he is a cog in a vast machine, required to give up certain rights and privileges which he has enjoyed and to which he feels entitled. He is subjected to military discipline, and is placed among strangers. It is easily understandable that a great strain is put on his power of adjustment. He finds that more demands are made of him, more responsibility is placed on him. He is compelled to undergo certain hardships, such as participating in maneuvers, and when a state of war exists, he is faced with the possibility of death or injury.

All these new adaptations are, from their very nature, difficult for the normal man, to say nothing of the unstable one. It is obvious, then, that many men will fail completely when these new adjustments are thrown upon them, and a frank psychosis will result. Many conflicts present themselves in the nature of behavior problems and a breech of discipline, which sooner or later brings the man into conflict with military law. It is the purpose of this paper to discuss the important angle of military discipline, to explain its purpose, and thereby to help the person to effect a more healthy readjustment from civil to military life.

The subject of military discipline is little understood outside the Army and, it must be confessed, is not always viewed in its proper light even within the Army. The difficulty may lie in the fact that most people either do not, or will not, grasp the proper meaning of military discipline, its nature, its purpose, its necessity, and finally, most important of all, its spirit.

Living within an atmosphere of strict discipline from the cradle to the grave, most persons fail to realize this because only a gradual adjustment is necessary. Practically every experience through which we pass and through

*From the Neuropsychiatry Division, Office of the Surgeon General.

which we acquire knowledge is in the nature of a disciplinary correction inflicted upon us by some agency of nature or of civilization.

Outside of military circles the average man recognizes fully the necessity of discipline in his family relationships, his business, and his relations with his fellow men. This is made easy for him to understand, since he is familiar with the reasons and conditions that surround the rearing of a family and that must necessarily govern the relations of men in civilized intercourse. All this information is gathered gradually by the average man, and there is no necessity to familiarize himself with it or to make a readjustment to it rapidly.

On the other hand, the average man is not familiar with conditions in the military service or, if he has some information, it is, no doubt, based on false information and is colored by fancy or rumor. Ignorance of a situation always provokes a reaction of fear, and when a person has knowledge of a situation he tends to lose at least some of the fear. It follows then that when the man does not understand the reasons for the rules and regulations required by military discipline, he is more than likely to view them with fear and intolerance. Even within military circles, among men who should be familiar with the reason and spirit of military regulations and discipline, many make the serious mistake of confusing the exercise of authority with the maintenance of discipline. In brief, they appear to think that discipline must be maintained wholly for the purpose of upholding their authority; and again, both outside and inside military circles, many fail to understand the spirit upon which true military discipline is based and must be based. Failing in this, they fail altogether, for the simple reason that men can understand the principle of military discipline only when they appreciate the underlying spirit.

Without the proper spirit there can be no such thing as discipline in any army. Proper discipline should, in no sense, be based upon the fear of disciplinary correction, since in this instance we have merely the blind obedience of the schoolroom type of discipline. The discipline on which a successful army must be built is a different kind; a kind that endures even when every semblance of authority has vanished, when the leader of the team has fallen, when members of the team are dropping out one by one, and when the only driving power that remains is a strong and unconquerable spirit of attainment. This concept gives us at once a working definition of military discipline: the spirit of the team.

Oftentimes the question is asked, "Of what necessity is military discipline?" The answer is readily found in the necessity for teamwork in any understaking, irrespective of whether it be in business, on the baseball or football field, or in the training of a vast army.

One element of good discipline is the fear of losing the respect of one's fellow members of the team, whether he be officer or soldier. This desire for esteem is one of the essentials of good military discipline. It is to be seen in all trained and disciplined units, the members of which feel for each other a natural respect and admiration. The knowledge that he enjoys the respect and admiration of his fellow soldiers is a source of the greatest pride to each member of the unit. The desire to retain this respect, to be looked upon as a worthy member of the unit, will greatly lessen the fear of injury.

In our present emergency we are attempting to inculcate in the minds of our soldiers the necessity of protecting our country, of taking the offense, and of bringing the war to a successful conclusion as rapidly as possible. Ideals have been set up, and the soldier must be helped to realize that he is fighting for a cause. He must be aided in finding satisfaction in serving such a cause and in expending his energy for that cause. It is needless to point out that Pearl Harbor and the subsequent events have given us the cause. The soldier must be physically developed, trained to conserve health, and he must learn to perform with technical skill his part in every incident as a member of the great team of which he is a member.

Besides these qualifications he must have the mental attitude of a soldier. To attain this proper attitude is an important step; there is an ideal characterized by the tendency to correct action and supreme satisfaction in such action.

In a short treatise Pew* places considerable stress upon the process of acquiring proper military habits and gives four maxims:

1. Select the habit.
2. Demonstrate the habit.
3. Secure abundant and genuine practice, with every effort of will and attention directed toward acquiring the habit.
4. Allow no exceptions.

Under this grouping this author classifies military bearing, courtesy, putting forth physical and mental efforts at the highest possible level, mental and physical self-control, neatness and order, smartness, exactness, and promptness; subconscious obedience, mental alertness, and confidence; and last but not least, teamwork in all military efforts. The old maxim "A chain is as strong as its weakest link" applies more than ever to the military forces of this era. Likewise, the same maxim applies individually to both officers and enlisted men.

It is held by many civilians and civilian agencies that military discipline would be desirable for those men who have failed to make a satisfactory adjustment to civilian life. It is to be pointed out that the Army is one of the elements of national defense, and its present mission is one of preparation for offensive and defensive warfare. To forge into that great team links that are defective or weak is to invite disaster. The Army is in no sense a social service or a curative agency. It should not be considered a haven of rest for the wanderer or shiftless, or a corrective school for the misfits, the ne'er-do-wells, or the chronic offender. Furthermore, it is neither a gymnasium for the training and development of the undernourished or underdeveloped, nor is it a psychiatric clinic for the proper adjustment of adults who are in need of emotional development and guidance. The man entering the Army will have to assume one of the greatest of obligations: that of protecting his country and its ideals. Therefore, there is no place in the Army for the physical or mental weakling, the potential or present behavior problem. If a man is a behavior problem in the community, he will certainly become a more intensified one in the Army.

It is to be further stressed that many men with abnormal personality traits are capable of satisfactory adjustment in civilian life. For this class there

*Pew, W. A., Maj. Gen., M. N. G.: *Making a Soldier*, 1917.

are in civilian life numerous avenues of escape which are closed to them when they enter the great team of the Army. Necessarily, teamwork of any type, more especially the Army, requires that a man readjust himself to a more or less inflexible and limited environment. When thrown upon their own meager resources of adaptation to Army life, requiring contact with all types of personalities, with limited and necessarily circumscribed opportunities for self-expression, many who are just able to adapt themselves under the most favorable conditions will not fit into that one iron mold which experience has taught is essential to military success. It is well to point out that over 50 per cent of the present beneficiaries of the Veterans' Administration are men of this type who were accepted in the Army during World War I.

The average selectee coming from the average American home has received the care, protection, and indulgence of fond parents and friends. They have made an effort to protect him from disturbing and disrupting influences that might interfere with his normal development. His parents have been interested to see that he wore the proper clothing and had the protection for all types of weather. New problems were taken over by his protectors who either solved them for him or helped and advised him in his own solutions. He has been guarded, protected, and steered, while his personal responsibilities have been at a minimum. He has not been trained to accept life as it really is.

Our soldiers come from all walks of life—from distant points in our country, from farm and factory, from colleges and benches; the rich and the poor, the educated and the illiterate—all are thrown together into a heterogeneous mixture subjected to the same military discipline, the same routine, and the same regulations. The soldier is called upon to recognize, appreciate, and conform to the wishes of others about him. He must live in close contact with his fellow soldiers and adjust himself to their method of living.

The transition from civil to military life will be made much easier for him if he understands the necessity for military discipline, the spirit of the team, and the real meaning of it. Americans are well adapted by their education and recreational experiences to realize the importance of teamwork, but sometimes it is necessary to point out to them that military discipline is a preparation and is necessary for the development of good teamwork.

It is astonishing how well and how rapidly recruits adapt themselves, even under the most difficult situations. It is the duty of each officer to keep these situations in the foreground and to take every opportunity to advise and counsel the men placed under him for proper training in military life. Each officer should regard himself as a member of a team in which each of his soldiers is an important member. Thus is built up a chain forged of confidence and respect one for the other, which will provide a pillar of mutual strength, both mentally and physically, when times of stress are greatly increased. It is, then, through military discipline that a strong, efficient team with high morale can be developed that will satisfactorily achieve the goal set for it. By understanding the reason for it, the man is enabled to make the transition from civil to military life in a more satisfactory manner.

WAR NEUROSES*

MAJOR NORMAN Q. BRILL, M.C., U. S. ARMY

INTRODUCTION

THE subject of war neuroses met with little interest and came in for little discussion until the World War. The subject became a vital one and has continued to demand attention ever since. It was during the war that for the first time such large numbers of individuals suffering from nervous disorders confronted the public, physicians, and government agencies. Psychiatry, a field of medicine which to a great extent was practiced in crowded institutions behind locked doors, was forced into the open and into its lap was thrust a problem which it has not yet fully solved. And now again it is to be given a task that will keep it occupied for many years to come. It is, therefore, important that physicians in the armed services and others who have occasion to deal with the psychiatric patient of preparedness and of war be familiar with the present-day concept of war neuroses.

DEFINITION AND MECHANISMS: IMPORTANCE OF PREDISPOSITION

Since war now embraces civilian as well as armed forces, the term will now necessarily be applied to both groups. Under war neuroses have been included a great many varieties of conditions. The diagnosis of exhaustion neurosis, shell shock, concussion neurosis, fright neurosis, and neurocirculatory asthenia have been applied to the manifestations which were so prevalent in soldiers during the World War. The symptoms were varied and consisted of tremors, inability to stand or walk, blindness, paralysis, stammering, and loss of voice. Many soldiers suffered from nightly frightening dreams and awakened with intense anxiety. Others complained of marked weakness with fatigue brought on by the slightest exertion, palpitation of the heart, or of dizziness or faintness, headache, or pains referable to practically every part of the body.[1]

The occurrence of such large numbers of these cases suggested a specific relationship between these conditions and war, and led to the naming of these conditions war neuroses. Referring to the World War, one authority stated that it is noteworthy that since the war and in the decade or two before it, such gross hysterical phenomena were only rarely met with in civil practice.[1]

However, it was observed that many soldiers developed the symptoms after slight or no injury during combat, behind the lines, in concentration camps away from the front, and in training camps at home. Also, the war neuroses differed little in their symptomatology from those of civil practice.[1]

The London correspondent of the *Journal of the American Medical Association* wrote the following in February, 1940:[2] "During the last war, the

*From the Neuropsychiatric Section, Station Hospital, Fort Bragg, North Carolina. Reprinted from The Military Surgeon 90: 390 (April), 1942.

large number of neuroses engendered by fear, shock, physical and mental strain or lack of sleep caught the medical officers of the army unprepared with any organization or agreed method of treatment. These neuroses were popularly called 'shell shock,' for it was supposed that they were due to the physical effects of high explosives. But it was found that similar symptoms occurred among men who had never been exposed to explosives and were well known in civil life. Moreover, many men who were blown up or buried beneath debris to the same extent returned to duty without suffering any permanent ill effects. The minister of pensions convened a conference under the chairmanship of Lord Horder to advise the government as to the general principles for dealing with these cases. Its report has just been presented and issued to the medical services." The report points out that most of the neuroses took the form of either an anxiety state or hysteria. The anxiety in all the cases was far out of proportion to the cause.

"In 1920 the army council appointed a committee to collate the medical experience of the war for future use. The committee reported: 1. The term 'shell shock' has been a gross and costly misnomer and should be eliminated. It is a catchword which reacts unfavorably on the patient and others. 2. The war produced no new nervous disorders. Only 5 to 10% of the cases that were called shell shock suffered from genuine concussion—while 80% consisted of 'emotional shock'—either acute in men with neuropathic disposition—or developing slowly as a result of prolonged strain and terrifying experience, the final breakdown being sometimes due to some trivial cause. In differentiating cases of concussion from those with emotional shock, it is well to remember that though patients with emotional shock may say that they became unconscious, careful questioning will show that they can recall most of their experiences."

Many cases now in training in Army camps are entering hospitals with nervous disorders. During wartime these cases might be called shell shock, if they started during a bombardment and were seen by physicians who were not familiar with the true nature of the condition.

In a vast majority of cases of neuroses that are being admitted to the hospital at Fort Bragg, a history of long-standing nervousness can be obtained. Many of these individuals frankly admit that they are no worse for being in the Army—that they "have always been that way." No statistics are available at present, but it is rare to find an individual whose nervous trouble began after enlistment or induction into the Army.

If the reaction, then, is not specific for war, it becomes necessary to explain the appearance of such large numbers of cases. It is important to consider first the question of predisposition to neurotic disorders. Individuals vary markedly in their abilities to tolerate difficult situations, as they do in adjusting to new situations. Some always worry while others are not fazed by the greatest tragedy. The "adjustment threshold" varies markedly in different individuals. It is understandable that a hypersensitive, excessively irritable, impulsive, self-centered, infantile and moody person can "take less" than a well-adjusted mature individual and will decompensate sooner when exposed to the same stresses and strains.

"In our hastily formed Army, especially under the draft system, there is a great demand on each soldier for rapid and violent adjustment. Men without any previous military experience, drawn from every conceivable walk of life, are thrown together and subjected to the same discipline, regulations and routine. It is astounding how well and how rapidly many will adapt themselves. However, many others will do poorly and hysterical reactions, psychoses and full guard houses are more than dead weight about the neck of an armed force."[8]

In *Circular Letter No. 19* of the Surgeon General's Office it states: "Not all persons are adaptable to restrictions and inhibitions of personal desires and comforts, to deprivation of rest, food, or shelter, or to the extraordinary demands for prolonged physical and mental activity often imposed by active military service. It must be remembered that many persons with abnormal personality traits who are capable of satisfactory adult adjustment in civilian life, in which numerous avenues of escape are available, will be a total loss to adjust themselves to a pattern which is more or less inflexible and, of necessity, delimited and circumscribed as to self-expression. When thrown on their own meager resources of adaptation in a military environment, in contact with all kinds of personalities, some who are just able to adapt themselves to life under the most favorable conditions, will not fit into the one iron mold which experience has taught is essential to military success."[3]

The symptoms which the patients develop under stress of training or combat are unconscious. They serve a purpose and are defense reactions to danger. The vast majority were not malingerers. Just because these soldiers had a sense of duty, esprit de corps, and of patriotism and could not honorably or safely run away from combat, they developed the unconscious conflicts and consequent symptom formation. The symptoms are for the most part hysterical. They are the result of a conflict between the instinct of self-preservation and the ideas of duty and self-respect. They satisfy the patient's ethical requirements and provide an escape from duty on the ground of physical incapacity.[1]

Man like other animals possesses instincts among which are the reactions to danger. He may stand and use his instinctual mechanism of defense to preserve himself—or flee from danger, not only to seek cover but to create as wide an interval as possible between himself and the instruments that seek to destroy him. The act of warfare meets these biological requirements of defense up to a point where there are trenches and Maginot Lines and organized retreat in the face of overwhelming odds. But the soldier cannot flee before the enemy just because he himself is in danger. He is no longer an individual, but an integral part of a battalion or company. The necessity for courage, loyalty, and self-denial were impressed upon him. Automatic obedience and strict discipline are instilled so that he will react to orders and not to impulse or instinct.[4]

However, "the individual soldier comes into a war with his own personal peculiarities. He comes with his own system of controls which have already in civilian life canalized his instincts along social channels. Further back in his childhood, his infantile aggressiveness and other instincts were subjected to a variety of controlling influences which modified them in such a way that his instincts and biological needs are only satisfied along prescribed socially acceptable

lines. . . . But however much this controlling part of the self is accepted, a perpetual state of strain is present deep in the nature of the mind, so that given sufficient provocation these submerged and now only partly statisfied instincts seek opportunity and find opportunity for operating."

"Frequently in examining the deeper psychology of the neurotic patient of the war, one found many men who stuck patiently to their duties, but who would, after a time, as the result of repeated provocation, break down under the strain. The controlling force, the better self, was no longer able to stand up against the insistent demands of an instinct which demanded either an escape from danger or an aggressive outburst. Powerful conflicts were produced between the instincts on one hand and the controlling force on the other. Where the natural self could find a way out, the soldier was able to solve his conflict by a variety of means, sometimes not laudable from the standpoint of morale . . . by reporting sick, getting around a noncommissioned officer for a soft job, or even courting the prospect of a slight wound which would allow a man to return home with mental peace and the semblance of honor. But this act could not easily be practiced and instead, when the bursting points were reached, hysterical reactions appeared. They were nature's way of obtaining some measure of adaptation, an adaptation which is in the nature of a compromise between instinct on one hand and conscience on the other."

"In cases of hysteria which had lasted sometime and were not cured immediately by the rough justice of disciplinary action or the tactful action of a wise medical officer, the reaction to war danger and stress became linked up with other conflicts in the mind which existed before the period of war service. No soldier came into the war with his mind a clean slate; it had already been written over with the story of his past experiences and conflicts. Former dangers and conditions of insecurity had either been met or had set up difficulties. Conscience had already made the coward and the courageous. The relatively mild analogues of war conflicts had already existed in civilian life. (There had been stresses and strains and causes for anxiety before.) It, therefore, did not take much time for the neurotic reactions to the war to weave themselves into the pre-existing neurotic disposition which had grown up in peacetime. It was for this reason that Emanuel Miller came to the conclusion that the cure of the hysteria of the war became in a large measure the resolution of mental problems of peacetime. Many patients with wartime neurosis, particularly those who broke down early, were found on deep analysis to be associated with long-standing feelings of insecurity. Such men were found to have spent their lives either in sheltered places or had old family ties which had thrown the responsibility for security not upon them, but upon their parents. . . . To them the establishment of new ties was difficult. Strangers could not be tolerated, new surroundings could not be assimilated. They felt themselves like strangers in a strange land and in a strange land full of dangers."

"One of the peculiar aspects of human psychology, discovered through the work of Freud, is the depth to which a man can really love himself. This love of self is not merely an expression of the self-preservation instinct, although this enters into it, but a primitive, childish, self-esteem which cannot be wounded.

Persons in whom this trait is strongly developed succeed in life admirably when they receive praise and become the centers of attention. They are not only pathetically preoccupied with their own achievements, but are sometimes even satisfied with their own selves as audience. They are proud of their bodies . . . and are literally in love with themselves. In warfare, such characters find it difficult to fit in with the group life of a regiment unless it affords them opportunity for self-expression; and when they are courageous, as they may be, it takes the form of seeking for decorations and applause. Such men, however, are terrified at the prospect of a wound, and the possibility of injury rules out all idealism. They are not the individuals who would face death for a cause. This type is prone to hysterical manifestations, to fugues and sometimes to major mental disorders. They cannot face the horrors of war, not because of sympathy for the slain, but because they identify themselves with every mutilation and death which the soldier has to witness. . . . Stated simply then, it is the conflict between conscience and instinct that can be regarded as the central motive around which all the clinical manifestations seem to collect."[4]

A clinical survey of the first group of invalid soldiers to be returned to Australia from abroad reveals some interesting facts.[5] Of 208 cases studied, 61 were due to diseases of, or injury to, the nervous system. A great majority of the patients suffering from anxiety states gave a history of previous nervousness or breakdowns. Careful inquiry into the past histories of these patients showed that they were capable of "carrying on" in civil life in spite of minor breakdowns; but the strain of military life in active service quickly revealed their mental instability. A large number might have been excluded from the Army if a truthful history had been given in the first place.

Captain John M. Caldwell, of the U. S. Army, reported the results of an intensive study of 100 American soldiers who developed psychoses during peacetime.[6] His conclusions were "the cause of schizophrenic psychoses in the United States Army is not found in any peculiar or particular demands of the service. However, the change from a familiar to an unfamiliar environment with added stresses and strains, probably plays a part in bringing latent trends to the surface. Abnormal sexual drives to a large degree are associated with the development of the psychoses and probably act as precipitating factors."

A report was published of 200 consecutive admissions to the Christian Street Hospital in Canada, in the year period from October, 1939, to September, 1940.[7] The cases included constitutional psychopathic inadequacy, mental defectives, epileptics, psychotics and psychoneurotics, alcoholics and malingerers.

Environmental and hereditary factors were investigated. In over 50 per cent the physical and mental health and economic status of the families were classified as poor or bad. Only 68 per cent showed both parents alive when the patient reached the age of 14. In eleven cases, parents were separated, seven were brought up in an orphanage, two had been adopted, and two were illegitimate.

With regard to education, thirty-two were illiterate and one hundred did not pass examinations on leaving public school. Most of these left school for no good reason. Sixty per cent had no trade; 51 per cent have had long periods of

unemployment, no settled occupation or required assistance from the family or authorities; 17 per cent had been in difficulty with the police. This included arrests for vagrancy, drunkenness, theft, and assault. Twenty-two cases were backward and eight had attended special school for backward children. Eighteen gave a definite history of a previous psychotic episode, seven of whom had actually been in a mental institution. Thirty-five had required attention for neurotic disorders prior to enlistment.

It was felt that the unsuitability should have been obvious in a majority of these patients on enlistment or in the primary training period. Often it had been recognized that the man would not make an efficient soldier and nothing was done about it. They were sidetracked on regimental duties, fatigues, etc.

In only twenty-six were strain, change of surroundings, alteration of diet, separation from families, etc., considered significant with regard to appearance of symptoms. None of those was definitely associated with war strain.

IMMENSITY OF THE PROBLEM

Even before our nation entered the war in 1917, many warnings were sounded by the French and British concerning the grave seriousness of neuropsychiatric disorders in the armed forces of that day.[4] The seriousness was emphatically brought home by a report finally rendered by the chief of the division of neurology and psychiatry of the United States Army on September 5, 1918: "Everything seems to point to our soldiers developing neuroses to a degree even greater than has occurred among the British. . . . The conditions of American life have been such that a young man suddenly taken from his surroundings where he more or less always had his own way, where obedience was never necessary, where he was taught that he was the equal of everyone, suddenly taken from surroundings of that character and forced to obedience, forced to face all this war . . . it would not be surprising if he showed his reaction to the change by developing a neurosis. . . . French neurologists have spoken of the excessive nervousness of American soldiers who have been under their care."[8b]

It developed that "whereas mental illness had been almost wholly ignored and the medical advances before the war dealt almost exclusively with physical diseases, the wide prevalence of the neuroses among soldiers was apparently leading to a revision of the medical and popular attitude toward mental and functional nervous diseases, and stimulating widespread interest in their observation and study."[8a]

"Many things were learned quickly in the war of 1914 to 1918. Although many physical disabilities could be waived, and although many of them disappeared with treatment or favorable conditions of military training, it was usually the opposite in cases of nervous or mental diseases. Such men were only too often singled out only after a considerable period of training, during which time they received pay, equipment and maintenance, wasted the time of instructors, interfered with training and filled hospital beds urgently needed for others. Many of them would have been better off to all concerned, if not even of material assistance to their country, had they been left in their accustomed

surroundings. If they became soldiers, they were almost certain to present eventually a serious economic problem to the nation in the form of government hospitalization and care."[8d]

"Neuropsychiatry was a new field in the war of 1914 to 1918. It interfered with established military routine and order and no doubt had a struggle in hastily orienting itself in this new situation. Officers complained that if specialists did not cease eliminating the unfit, there would be no Army left. It was felt that training which transformed poor physical specimens into robust fighters could do the same for those who had nervous or mental disabilities. As a result, recommendations for rejection or discharge were often waived by line officers. Eventually it was discovered that the nervous and mentally unfit were greatly embarrassing the American Expeditionary Forces. On July 15, 1918, General Pershing urgently cabled the Chief of Staff that more intensive effort be made to eliminate such men. After this, rejections and discharges were carried through with less difficulty."[8c]

"Although many conditions were clear-cut and sufficient for outright rejection or discharge, others were more difficult. These proved to be constant sources of annoyance and trouble to the officers, forming the larger number of the absentees, the discontented, the inefficients, the inmates of the guard house, and the frequenters of the regimental infirmary. These were the cases which complained of being dizzy, faint and bewildered at critical moments."[8d]

"It was said that no other class of men made for so much mischief in the United States Army as did the feeble-minded. Their records prove that physical health, strength and ability to get along in civil life did not, in themselves, insure satisfactory Army service. The strange and exacting environment of the Army was too much for them."[8d]

"The need for routine neuropsychiatric examinations of commissioned officers was expressed."[8e] "A startling number of defects was found among those attending officers' training camps, and it was felt that if all candidates for commissions had been subjected to a thorough neuropsychiatric examination, many would have been rejected with advantage to the military service. In fact, this failure was said to be probably the outstanding defect of the neuropsychiatric service."[8f]

"That the initial examination was important was demonstrated by the fact that 27,836 neuropsychiatric cases, or 40% of the total reported, were discovered during the preliminary examinations of recruits and draftees."[8f]

"The United States Navy, too, was not without its difficulties. The psychopath received particular attention. Quoted newspaper stories demonstrated how undesirables were urged to enter the armed forces. For instance:

"Dec. 16. Thief dismissed so that he might join the Army. D. F. pleaded guilty here today on a charge of petty larceny . . . but an indictment against him charging forgery . . . was dismissed so he might enlist in the . . . United States Army."[8g]

"In a survey of inmates of naval prisons, it was concluded that 54% are men who clearly should have been eliminated at the recruiting or training station."[8h] "Another naval writer's experience points to the fact that the psycho-

path has more difficulty adjusting himself to the service than has any other type of questionable individual. A recruit in this classification is not amenable to discipline and he ordinarily cannot comfortably be assimilated in any part of the organization without having an influence on morale."[8i]

"Eventually it evolved that from April, 1917, to December, 1919, 95,577 officers and men (both Army and Navy) were admitted to hospitals for mental disease in this country and abroad, and 41,976 were discharged for disability incidental to mental disorders in the same period."[8j] "Also of 54,117 ex-members of military service hospitalized by the Veterans' Administration, approximately 60 per cent were hospitalized because of neuropsychiatric disabilities, and cost the government almost $1,000,000,000 in the past fifteen years."[8k] "Even with the exclusion of paresis, mental deficiency, psychopathic personality and chronic alcoholism, two out of five veterans receive pensions because of neuropsychiatric disability."[8l] "Three of seven men discharged for disability from the Army in 1939 were suffering from mental disease, and suicides ranked second as major cause of death in the Army for that year."[8]

Similarly in the British Army, statistics from the last war showed that one-third of the unwounded, and one-seventh of those discharged were permanently unfit because of functional neuroses and mental disorders.[9]

TREATMENT

With regard to treatment of patients suffering from war neuroses in the field, the first essential when the patients arrive at an aid post is to convince them that they have received no serious injury. When confusion, excitement, loss of memory and disorientation are the chief symptoms, rest, warmth, hot drinks with plenty of sugar, and a dose of bromide or phenobarbital will be necessary. Restless or excited patients may be given a hypodermic injection of morphine or soluble phenobarbital combined with hyoscine. When hysterical symptoms predominate, an attempt should be made to remove them by suggestion.[2]

According to one English Army physician (Dillon), during the World War 63 per cent of the patients suffering from so-called acute anxiety states were able to return to duty after treatment which consisted primarily of rest and sleep, and relapses occurred in only 5 per cent.[9]

In cases that do not respond quickly, the prognoses are not as good and more intensive and prolonged psychotherapy is necessary. Such procedures as hypnosis, suggestion under narcosis, suggestive physiotherapeutic measures, and psychoanalysis have been used by various authors with reported good success. Many patients will, no matter how treated, become chronic invalids and require government care for the rest of their lives.

The major factor in the prevention of war neuroses is the detection and early rejection or elimination of the emotionally unstable from active combat service. This can be done if there is a greater awareness of the problem in medical circles. Physicians on induction boards should have a psychiatric as well as physical orientation and approach. Any lack of psychiatric awareness that does exist is but a reflection of the state of affairs in the medical profession in general.

However, the lesson of the World War was well learned, and it is significant that the Surgeon General has requested that medical officers examining applicants for the Army be especially alert to detect all those with any mental or nervous abnormalities who later may disrupt discipline and morale, retard progressive military training, occupy hospital beds urgently needed for acutely ill patients and finally become an economic burden to the government.[3]

If greater attention were paid to the following statement of the Surgeon General, this immense problem would in great part be solved: "The Army is one of the elements of national defense, and its present mission is one of preparation for an offensive-defensive type of warfare. It is in no sense a social service or a curative agency. It is to be considered neither a haven of rest for wanderers nor a corrective school for misfits, ne'er-do-wells, feebleminded persons or chronic offenders. Furthermore, it is neither a gymnasium for the training and development of the undernourished or undeveloped nor a psychiatric clinic for proper adjustment to adult emotional development. Therefore, there is no place within the Army for physical or mental weaklings, potentially psychotic or prepsychotic persons or behavior problems. Men who present behavior problems in the civilian community will certainly present intensified problems in the service."[3]

NEUROSIS IN CIVILIAN POPULATIONS

With regard to the problem of war neuroses in civilian populations, the general experience in Britain so far bears out the report of a conference of medical men convened before the active stage of war began. They stated that an exaggerated estimate had been formed of the liability of war to produce nervous breakdowns. This has received substantiation since the intensified air raids on Britain have been in progress, for few nervous breakdowns have occurred in spite of the suffering and material loss.[10]

The best remedy against panic and disruption for civilian populations lies in the active participation of as large a section of the population as possible. A lesson is to be learned from the Germans, who state there are no shoemakers in Germany any more, they are all fighters on the shoemaking front. Democracy too often leads to an attitude of what do I get, with a disregard of what can I give.[11]

Aggressive impulses of the people should be mobilized along certain definite channels. Each individual as far as possible should be given an active part to play. Training in first aid, instruction in modern methods of warfare, the nature and effects of high explosives and gases should not be kept as a mystery from the average citizen. He should also be taught the importance of the so-called fifth column in modern war and what measures are necessary to counteract it. Another error has been an excessive concentration of the public mind on safety first. There has been far too much talk of where to hide and how to protect one's own skin, of keeping up the morale of the nation, and of preventing panic. There has been too little talk of how to defeat the enemy. People were getting the feeling that one had only to sit and wait long enough for the enemy to be defeated without personal danger. This was the philosophy of the Maginot Line and it was a psychological disaster. It led to the feeling that we had only to produce enough machines, enough concrete and enough airplanes and to pour out enough money to win the war.[11]

WAR NEUROSES. EXPERIENCES OF 1914-1918*

Lessons for the Current Emergency

Douglas A. Thom, M.D., Boston, Mass.

IT IS difficult to discuss the war neuroses as they occur during active service without thinking in terms of what precedes active service, and although you have undoubtedly heard a good deal about that phase of military activity, it may be necessary to repeat a bit of it in order to get oriented. I think we can say that the last war contributed more to psychiatry than psychiatry did to the war. I mean that the last war gave psychiatry a certain professional standing which has continued, and after the war it was found that various foundations and organizations recognized psychiatry as a branch of medicine worthy of support. I said recently that the problem of war neuroses is a three-dimensional problem. Its length reaches from war to war; the neuropsychiatric casualties of the last war still remain on our hands, and the effect of the current conflict already begins to reveal the unstable personalities in our civilian population and bring new casualties. The neuropsychiatric casualties of the two wars are overlapping. We still have some 68,000 neuropsychiatric disabilities in the government hospitals from the last war. The report of the administrator of Veterans' affairs indicates that they represent 58 per cent of all patients being cared for by Veterans' Hospitals. The economic aspect of the problem is appalling when one considers the money spent on treatment, training, and compensation. It can be said that the war neuroses begin early. They are long drawn out, they are difficult to treat, and they tend to increase for at least twenty-five years after the cessation of hostilities. It has been estimated that it costs $30,000 to care for a psychiatric disability from the time the individual breaks down until his death. We have some twenty-eight hospitals in this country caring for these 68,000 patients.

The provisions for detecting these potential neuropsychiatric disabilities before they get into service are shockingly limited and inadequate. The Government will employ a few psychiatrists at a rate of $15.00 a day and is expecting them to examine anywhere from 150 to 200 patients a day. I have pointed out to the administration that if one psychiatrist picked out but one potential psychotic every six and one-half years, he would save his salary. There is a pressing need for a careful psychiatric examination before induction of men into the military service.

The neuropsychiatric disabilities resulting from active military service represent what we call the war neuroses, and what the British used to call "shell shock." The latter term represented the viewpoint of British pathol-

*Lecture XII, reprinted from *Collected Lectures of the Metropolitan State Hospital*, Waltham, Mass., 1942.

ogist Colonel Mott at the time of the last war, who felt that "shell shock" was an organic condition produced by minute, petechial cerebral hemorrhages. The role of psychological factors in "shell shock" was minimized. It was, however, recognized eventually that a great many of the soldiers diagnosed as "shell shock" casualties had not been anywhere near a shell. This group of "shell shock" cases proved to be made up of most heterogeneous neuropsychiatric disorders, so varied that it would be of little value to classify them. In order of their frequency the neuropsychiatric disabilities of the last war were neurasthenia, conversion hysterias, anxiety states, and psychoses. We did see some mentally defectives, but they represented a small group, for about 30 per cent of all the individuals eliminated before they went into service were disqualified because of mental deficiency. There were nearly 70,000 cases disqualified as constitutionally unstable individuals, potential psychotics, epileptics, and feeble-minded.

The neuropsychiatric casualties must be considered in relation to three phases of the state of war: the period of mobilization, the period of active service, and the period of demobilization. It was recognized and the point was stressed during war activities and later in civil life that there are limits to the amount of physical and mental stress that any individual can withstand without breaking down in his adaptation to life. These limits are not static; they vary from time to time in the same individual, and they vary, of course, from one individual to another. I happened to be at the Boston Psychopathic Hospital when the last war broke out, and we had many individuals coming in immediately after war was declared. Their delusions and hallucinations were colored by the war activities, colored by what they were reading in the press and saw at the movies. In other words, it took no more stress in these particular individuals than the simple declaration of war to bring out definite psychotic symptoms and break down their adaptation to life. At the present time we find individuals who have been making a good adjustment to civil life under demands which have not been too successful, but who have developed all kinds of anxieties and hysterical manifestations under the stress of mere anticipation of being drafted. A mere threat of war is enough to break down what appeared to be a good adjustment to the demands of civil life. Many individuals of this type will be weeded out; others will get into active service and will go to the camps. There they will be subjected to the stress and strain of making an adjustment to army life in an environment where discipline is strict, where they have to adjust to groups of individuals living intimately, dressing and undressing and looking after their personal needs under conditions that are embarrassing to the shy and diffident individual, and being subjected to teasing, razzing, or becoming the "goat" of the crowd. These individuals, able to go through the first stages, begin to break down when they are subjected to stresses and strains of army life. Then, after war is declared, and as we begin to embark and think in terms of getting overseas, another group of individuals begin to break down anywhere from the port of embarkation up to the front-line trenches. There were, however, individuals who went through all these phases with no evidences of failing to meet the responsibilities and obligations of army life, but who broke down on the way back to the safety zone—a sort

of delayed reaction. If the war had continued, there would undoubtedly be many more individuals hitherto intact mentally and physically who would have developed neuropsychiatric disorders.

Studies made of the constitutional background and the psychopathic taints do not show a great deal of difference in the hereditary background of those who broke down and those who were sufficiently stable to carry on. In general figures it can be said that we found 5 per cent of poor inheritance in the "shell-shocked" soldiers. compared with 2.5-3 per cent in those who were considered stable. There was a difference, but it was not marked. There was, however, a marked difference in this respect between the soldiers who broke down overseas under battle, under the stress and strain of the firing line, and those who broke down before they went overseas. The latter showed a marked constitutional neuropathic disposition, and their neuropathic background indicated that they were definitely unstable.

In my experience, "shell-shocked" soldiers seen en masse on the wards did not measure up in their personality make-up to the average sick soldier cared for in a general medical hospital. If you went into a hospital for "shell-shocked," you would recognize in a relatively short time that you are dealing with a group of individuals who, on the whole, are rather inadequate. It is interesting, too, to keep in mind the effects of different types of psychic trauma on different individuals. We find a great many men who went through the war, went "over the top," were right in the thick of battle, were subjected to all the strains of active warfare, showing no evidence of strain, who came back and developed a severe neurosis during the economic depression which followed demobilization. We found many men carrying on perfectly well as soldiers overseas, who would crack-up after hearing that their wives were sick or that the son died. Different individuals seem to be affected by different circumstances, stresses, and strains. One individual seems to be more susceptible to fear and others to grief. A threat to one's reputation, loss of self-esteem and prestige are factors that affect some individuals more than fear or grief.

During the last war about 2 per cent of those engaged in active service overseas developed "shell shock." One may say either that the 2 per cent represented the wholly unstable group, or that the other 98 per cent were unusually stable. I think it is logical to look upon the 98 per cent of soldiers who withstood the test of active service as representing the normal individuals, while the 2 per cent, for some reason or other, represented the unstable group.

It is of interest to point out that those individuals who represented the top 10 per cent in their psychological examinations as given in the camps were the individuals who, on the whole, made the best soldiers. They were better adjusted, and more frequently were selected as noncommissioned officers. In the lower 10 per cent were found the maladjusted group, the individuals who got into difficulties. We found these individuals more frequently in the guard houses and among those who went A.W.O.L.* They were the boys who were teased and harassed by their companions. It is among this type of men that the "shell shock" was most frequently found. I think this observation will be substantiated by the observations made in camp as time goes on.

*"Absent without official leave."

The neuropsychiatric casualties at the front varied in numbers and depended a good deal upon the severity and duration of the preliminary engagements and skirmishes which preceded big drives. At Chateau-Thierry, for example, about 20 per cent of the casualties were neuropsychiatric casualties, because the man had been subjected week in and week out to stressful experiences before they went into the actual battle.

It is recognized that a neurosis serves a purpose in the life of the individual. It has a protective mechanism. Trotter used the term "herd instinct" to denote such attitudes as loyalty, patriotism, honor, etc. He pictured this herd instinct and the instinct of self-preservation as the two forces which came in conflict and could only be dissolved by the neurosis. We tried to evaluate just what purpose the neurosis served in a soldier.

If one thinks in terms of the war neuroses as being a protective mechanism, we have to go back some years. The war neuroses were first recognized, I believe, by the Russians in 1905 and 1906, and provisions were made to care for these neurotic cases. That was the first time any recognition was given to the fact that war produced mental casualties and that these mental cases needed consideration on equal terms with other types of war casualties.

In the last war, the medical men, the military authorities, the public, and the press accepted the fact that "shell shock" was an illness not due to any malicious intent on the part of the soldier. Thus, the "shell shock" became by the same token a legitimate way out of a difficult situation. When war began, the herd instinct was a major driving factor for most of the men who enlisted or were drafted in the army. The feeling of self-esteem, the honor in which the individual wants to be held by his friends, by the community, by the military authorities, and by everyone else with whom he comes in contact, and the propaganda, speeches, the bands and parades, the uniform, the pride in being a soldier, the fact, too, that becoming a soldier oftentimes solved a good many conflicts of one's civilian life, such as worries and anxieties of an economic situation, or of a marital or professional difficulty, all those things contributed in building up this herd instinct. To join the army, to go to war, was the thing to do. It gave the individual a sense of importance and a sense of security. It enhanced his feeling of self-esteem. Nothing else mattered. The herd instinct as it related to the war was high, and the instinct of self-preservation was quiescent. One was not thinking in terms of life and death but rather in terms of satisfying certain emotional drives. However, as one became more actively engaged in military service, as one approached from the camps to the ports of embarkation, certain aspects of the glory and the glamour of the uniform were lost by doing kitchen police work and being subjected to an iron-bound discipline of the army. A good deal of this herd instinct began to fade away. The enthusiasm began to subside, and the instinct of self-preservation began to rise. As they neared the front line, the herd instinct became counterbalanced by the instinct of self-preservation. In those individuals who carried on, of course, the herd instinct was always higher, and the instinct of self-preservation remained submerged, while in those individuals in whom fear, anxiety, the emotional tension were of such a degree that the sustained threats

to their physical security could not be held in check by the herd instinct, severe emotional conflict resulted. The "shell shock" or the neurosis served the purpose of satisfying both drives, for it was recognized as a respectable way out of a difficult situation. It allowed the individual to protect his own self-esteem, because "shell shock" was looked upon as a legitimate cause for military incapacitation by the officers, by the doctors, and by brother soldiers, and at the same time it satisfied the instinct of self-preservation. It was a solution of an intolerable dilemma.

There were three ways of solving the conflict between the instinct of self-preservation and the herd instinct. One was to get killed, the second was to get wounded, and the third was a neurosis. We rarely saw a "shell-shocked" soldier, a neurotic soldier, who had a wound. The wounded individual didn't need a neurosis. He was out of the situation by virtue of his wound. Occasionally, the neurosis developed among wounded soldiers when the time came for their discharge, and they were confronted with the situation of having to go back into active combat. On the whole, one did not find neurotic soldiers among wounded.

Another interesting observation is that the neuroses were less frequent among the professional military men than among men who went into military service from civilian occupations. Thus, the English Army was, so far as the officers were concerned, made up to a large extent of professional soldiers. It was somewhat different in our Army where an officer might have been an insurance clerk or a lawyer or a business man, who went to one of the R.O.T. camps, and in the course of six or nine months became an officer. I do not believe I ever saw an hysterical paralysis in an English officer. I have seen a few neurasthenics, but, on the whole, the war neuroses were relatively few among English officers. They were trained for a life job, and consequently, were better adjusted to stresses and strains of war. Among the American officers, however, we often observed individuals suffering from a paralyzed leg, paralyzed arm, blindness, or some other hysterical symptoms. I remember, also, two or three high ranking medical officers coming to hospital with an hysterical paralysis, the sort of thing you would not believe compatible with a physician's knowledge of the nature of hysterical symptoms.

The neurasthenia and hysteria were the most common types of neuroses encountered during the last war. We saw relatively few cases of conversion hysterias with physical incapacities like paralyzed arm, leg, blindness, etc., in officers. We saw them frequently in the soldiers. A soldier with hysterical incapacity invariably represented an individual who met and solved the conflict between his herd instinct and his instinct of self-preservation at once, without putting much into it. The neurasthenic was, on the contrary, an individual in whom the internal elaboration of neurosis was more insidious. He went in and out of the front line trenches, he may have a good many symptoms such as insomnia, perhaps some battle dreams, feeling of exhaustion and fatigue, tremors and other symptoms, but he kept going in and out until he reached the point where he was no longer able to carry on. The hysterical individual met that situation more crudely. He was satisfied oftentimes with a group of symptoms that seemed so completely incompatible with his education, his back-

ground, his whole understanding of what that situation meant. The hysterical soldiers, as a whole, were more easily treated than the neurasthenics. They recovered from their symptoms more easily also, because they were eminently suggestible individuals, but they were also very much less likely to remain without relapses.

It was recognized early in the war that acute cases of war neuroses had to be dealt with promptly. It was found that cases with anxiety states, with hysteria, and with neurasthenic symptoms, which were sent back to the general hospitals along with the general medical and surgical cases were most difficult to treat effectively. Oftentimes they would be picked up with the general medical cases and simply remain for weeks on the wards of a general hospital, getting little or no psychiatric attention, their symptoms becoming fixed, and as a result of being in the wards with medical and surgical patients with organic symptoms, the whole picture became more elaborate and difficult to treat. That situation was bad also for the physically sick patients, as you know. For these reasons, receiving centers were set up within 5 to 10 kilometers from the front lines with psychiatrists on duty who saw all sick men as soon as they came back from the front. Thus, many of the soldiers who developed neurotic symptoms in action got no farther back than perhaps 5 to 8 kilometers from the front lines where they were treated. Many of these were cases of acute fear reactions plus exhaustion and fatigue. From 60 to 70 per cent of all such cases were returned from these centers back to the front line trenches within forty-eight hours. These centers did a useful work in segregating the cases. If all the neurotic cases had been indiscriminately evacuated to base hospitals, permitting a long period for the neurosis to become set before treatment could be started, undoubtedly many soldiers with milder neurotic states would never have returned to the front, and a large number of soldiers who well might have developed a chronic neurosis were thus salvaged for the service.

The amnesia cases represented a particularly interesting group, because these individuals attempted to solve their conflict between the herd drives and those of self-preservation by completely obliterating the memory of the intolerable situation. "Forgetting" allowed the man to carry on with duty, and one rarely saw the amnesic patient with any other neurotic symptoms. Sometimes the amnesia would be restricted to a rather short period in the individual's life, covering a space of time of perhaps a day or two preceding some trying event and extending beyond for two or three days. Other individuals would have a complete anterograde and retrograde amnesia lasting for weeks and months, forgetting completely all that happened before and after the event which produced the amnesia. There were also peculiar types of partial amnesia with confusion in which the individual would remember people and certain incidents but couldn't identify them with any particular situation.

The therapy of war neuroses varied with the different schools of thought. Some felt the approach to these problems was through analytical procedures and others felt that suggestion and hypnosis were more useful. It was important that patients got in and out of the hospitals as quickly as possible, and

one had to think in terms of methods that were practical. For that reason, a large number of the conversion hysterias who were undoubtedly precipitated by suggestion were treated by countersuggestion aided by faradic current ("suggestion armée" or "torpillage" method of the French). A patient in capacitated by an hysterical paralysis of the leg would be carried along at the hospital somewhat as follows: The doctor would take a history and endeavor to get on friendly relations, finding out all he could about the early history of the soldier's home life, interests, hopes, ambitions. attitude toward the war, resentments, attitude toward superiors, homesickness, fears, etc. Then a careful neurological examination would follow with any other examinations and laboratory tests that seemed advisable. Every psychiatrist had his own technique of treating his patients. One might start out as follows: "Now, John, you want to get well. You want to get over this trouble. You don't want to carry a bad leg around with you all your life, do you?" John would usually agree that he did want to get well. He would be taken off the ward to a treatment hut with a medical sergeant or corporal, and the psychiatrist would make another short speech, saying, "John, we are going to treat you and you are going to be absolutely cured when you go out of this place. That, I take it. is what you want?" Nothing short of that dogmatic assertion had any real value as a suggestive measure. John would say "Yes," a little less enthusiastically than he had before. There are a few psychological tricks, such as, "Lock the door, Sergeant." Then you tell John that the treatment may be very short or it may take some time, "It may take five or ten minutes, or it may take all day, John, but when you get out, you are going to be well; that is the important thing." "Now, John, this may be a rather painful procedure—does that bother you?" He would usually say "No," he just wanted to get so that he could walk. The hysterical patient was always very urgent in protesting against the illness and wanting to get over it. The electrical current would be applied and increased as found necessary, with continuous suggestion that function was to be restored. It is purely a matter of suggestion, and in a surprisingly short period, with the use of the current and help from patient, the muscles would contract; then the contractions would take place without the current. You show him, talk about it, demonstrate to him that there was function. Under the stimulation of the current the leg would jerk, and he would get cramps, some of them painful, and under the excitement he would find that he could move the leg, stand on it, walk. It was always desirable to spend a certain length of time with the patient after function had been restored, explaining the purpose of the paralysis, how it may come back under stress, and ways and means of preventing a recurrence of difficulty. After restoring function, the patient always was returned to his ward for the psychological effect on other patients. Went out in a wheel chair, returns under his own power! On the other hand, if a patient was not cured at once, he would not be returned to the same ward for obvious reasons. The neurasthenics and other types of neuroses did better under some modification of analysis, persuasions or re-education.

Sixty-five per cent of the cases of war neurosis were sent back to active duty, 30 per cent went to the service of supplies, and 5 per cent were found

unfit for military duty. The classifications used for the neuropsychiatric disorders were neurasthenia, psychasthenia, hypochondriasis, hysteria, anxiety neurosis, anticipation neurosis. Most of the anticipatory cases were those individuals who developed neurotic symptoms before they had engaged in any actual war activities. The individuals suffering from effort syndrome or neurocirculatory asthenia were common. They are being recognized at the present time by the examining boards and are considered as being unsuitable for service. There were many cases of exhaustion associated with a mild anxiety state.

I believe that the effects of the present war will not be particularly different from those seen in the last war. It is difficult to see how we can eliminate the unfit when the time of psychiatric examination is limited to six or eight minutes. In many of these cases the unfitness of the individual has to be determined by the evidence obtained from the individual's past history rather than on the basis of signs and symptoms the psychiatrist may discover during a short examination. Already examiners are finding men in the Army who have been in state hospitals or were released from state hospitals only a few weeks before their induction into the service. The attitude of some of the military authorities is still expressed thus: "You give us the men, and we will make an Army out of them." The fact, however, is that a man may be able to make a very satisfactory adjustment to civil life, and yet this is no guarantee that he will make a good soldier. The demands of the Army on the individual are quite different from those of civil life. Many a neurotic individual makes a fairly good adjustment to civil life, he may fit into the social scheme of things, he may be a pretty good father, husband, friend, and neighbor, and yet he is quite unsuited to meet the demands of military life. It is not possible to eliminate all the potential psychoneurotics. A certain number of them will be picked up before they get into service, others will break down when they get into camps, and still others on the way to battle lines. On the whole, it seems to me we are going to be confronted with the same kind of problems during the period of mobilization and active service as we had in the last war.

I spoke of a period of mobilization and of active service. I think the period of demobilization is a period quite as important in creating the neurosis as any other in the experience of the soldier. The methods utilized in demobilizing, and the various services that the government has set up for compensation treatment of war disabilities, for training in various professions, have created potent motives for neurotic manifestations in certain individuals. I believe that following the last war these procedures of demobilization created many neurotics. When you pay a man for being sick, penalize him for getting well, when you push him into highly specialized organized occupational schools, giving him a false idea that he is going to become a good engineer, good public accountant, while he is totally unsuited for that sort of thing, you create a great gulf between man's fanciful ambitions and the grim reality of his actual abilities to achieve these ambitions.

The war neuroses are not different from the neuroses we see in civil life. I think, however, that war neuroses are much more amenable to treatment than

the neuroses seen in civilian life. Created by suggestion, the war neuroses are readily helped by suggestion. There is a certain prestige of being an officer and in utilizing the therapy of suggestion. There is a greater prestige relationship between the soldier and the medical officer than there is between the patient and the doctor in civil life. In civil life, if the patient doesn't like one doctor, he can seek another. The soldier has no such rights. An important lesson we learned from the last war is that the nearer these neurotic manifestations can be treated to the place of their occurrence, the easier and quicker they are cured. If the neurotic individuals are treated at the receiving centers immediately behind the front lines and soon after their symptoms developed, a great many of them can be sent back within a short time. On the contrary, the most difficult cases to deal with were the cases evacuated from the front lines to general hospitals far in the rear. They just hung around and simulated symptoms seen by them in others, while their own neurotic manifestations would become chronic and fixed.

Question: Was there a difference in the incidence of "shell shock" and neurosis in the English and in the American troops?

Answer: I don't think there was any significant difference between the Americans and the British. We did, of course, make more careful examinations, poor as they were, before the induction into service than the British did. In England the men were thrown into service at first without much time for psychiatric examinations. They did have the same sort of sifting process in the British Army but not to the extent that the American Army had. The incidence of neuropsychiatric casualties was not particularly different.

Question: What immediate measures did you use for treatment of neurotics at the front lines?

Answer: Right at the front trenches these men were given rest. Reassurance was an important part of treatment. A good many of them had fear of being looked upon as cowards, and they were anxious to get back. Sedatives were used. It was a matter of bucking the morale of the discouraged soldier. Two out of three soldiers who came there from the trenches would be relieved after a night's sleep, rest, and reassurance that they were all right and not "yellow," and back they would go. They rarely were kept more than seventy-two hours.

Question: Did they go back to the same posts in the trenches or would they be transferred elsewhere?

Answer: About 65 per cent of the cases would go from the "triage" centers back to their own companies. The other third would be evacuated to base hospitals.

Question: Would a man be reassigned from the combat duty to kitchen or something like that?

Answer: This was done in some instances. They would get a Certificate of Disability marked one, two, or three, i.e., they were to go back to duty, or duty behind the lines, or they would be discharged. A number of those men were assigned to some type of service behind the front line.

Question: There is probably no other field than that of psychoneurosis in which the racial characteristics present themselves more distinctly. Is that your impression also, so far as the war neuroses are concerned? For example, the symptoms of conversion hysteria, such as hysterical paralysis, contractures, fits, blindness, seem to be more frequent among Latins than among Anglo-Saxons.

Answer: Yes. I think that is perfectly true in civil life as well as in military life. I suppose that is why method of "suggestion armée" or "torpillage" was originated by the French, for it is a method of treatment particularly suitable for conversion hysteria. We see relatively few cases of conversion hysteria in our large out-patient clinics. I doubt if there are seen more than a few cases a month in all the clinics of Boston of real conversion hysteria, while in the French clinics, I am told, they are seen much more frequently.

Concluding, I wish to repeat that the individual who develops a war neurosis, the malingerer, the fellow who tries to bluff his way out of the Army, the psychopath, the unstable individual, will not be a good soldier. It is far better to have on the soldiering job a man physically sick than a neurotic. The Germans don't recognize the war neurosis as sufficient reason to get out of service. They are using the neurotic in building roads and front-line trenches, under strict military discipline, subjecting them to all the dangers of front-line activity. We have no way of knowing how efficient such military measures really are in treating a group of inadequate individuals whether they be malingerers or neurotics. We do know, however, that these individuals do not make good soldiers. They certainly represent a menace to any organization, and neither the British nor the American Armies will probably resort to such measures.

"SHELL SHOCK" AND EFFECTS OF HIGH EXPLOSIVES*

D. Denny-Brown,† M.B., F.R.C.P.

THE term "shell shock" is rapidly becoming obsolete, though the clinical conditions it used to describe are by no means uncommon in the present war. Until I was asked to give this talk, I had not used the term for almost two years, following the findings of a British Commission which was set up in 1939, which recommended that the term would be dropped altogether. In the last World War millions of men in closely packed trenches were subjected to tremendous bombardments for months at a time. A mysterious kind of nervous disorganization occurred in those who were submitted to close shelling, and it was natural that this clinical syndrome should be thought to be due to the physical effects of explosion. It was difficult to deny some particular influence on the brain from the explosive force of the shell quite apart from direct injury to the brain from fragments. The nervous symptoms were often absent in those who had suffered severe direct brain injury. There began a search for some objective basis. Most of the patients suffering from shell shock did not come to autopsy. They were disabled for long periods of time, many of them with frank hysterical or neurotic symptoms, most of them labeled "chronic neurasthenia," some suffering from traumatic intellectual impairment, and some truly psychotic and requiring commitment. In the aftermath of the last World War thousands continued to attend special clinics and hospitals, receiving various degrees of pension for this disability, "shell shock." In the brains of the few who died without sign of external injury, pathologists reported finding in some no lesion of any kind and in others small petechial hemorrhages in the brain substance. It is now felt that such pathological changes as were reported were not necessarily present in those who survived and suffered from the clinical picture which was called "shell shock." Thus, in a case described by Mott, the man died from an explosion in a munitions factory but was known to have been exposed to carbon monoxide, which alone could account for petechial hemorrhages in the brain substance. Others may have suffered from fat embolism which also gives rise to such hemorrhages. At the time of the Spanish Civil War there came reports that bombing may cause death in a very mysterious way; tales of patients found dead after the bomb explosion who showed no sign of external injury and in whom at autopsy no cause of death was to be found. Again it was supposed that some mysterious effect of high explosives damaged the nervous system. One was naturally very skeptical of such reports, because in ordinary civil life dislocation of the cervical spine with transient compression of the spinal cord may cause death without more than a small softened segment. And so it is suspected that

*Lecture XIII, reprinted from *Collected Lectures*, the Metropolitan State Hospital, Waltham, Mass., 1942.

†Professor of Neurology, Harvard University, Major R.A.M.C., now demobilized for research investigations.

such dislocation may have caused these mysterious deaths in people who were killed by sudden explosive violence. Another rumor dating from the first World War was that if men were in a trench and a very high explosive shell fell near by, then in some way the ground was shaken and the people in the trench were concussed. It is difficult to find any adequate foundation for this, which is obviously related in some way to the problems of "shell shock" and unexplained death from bombing.

There are many points of resemblance between "shell shock" and "traumatic neurosis." As you know, many who have had a head injury in ordinary civilian life are particularly liable to nervous symptoms for a number of years afterwards. That condition has also led to differences of opinion. In its prolonged posttraumatic anxiety symptoms and variable association with actual cerebral damage, this syndrome is seen to be closely related to that of "shell shock."

I think some case histories will best give an idea of the nature of the problem. Most patients close to an explosion of bomb or shell suffer from direct wounds, such as foreign bodies in limbs, body, or skull, fractures of limbs, and injury to the chest. If one looks for what we call pure "shell shock," one must seek the patient who had no external injury from the explosion but who was unconscious. There are very few such patients, and their persisting symptoms are of emotional type. Many have had a definite but trivial injury, such as a cut scalp, and suffer later from the same symptoms.

Case 1.—An infantryman, aged 29 years, had survived several severe bombings without any symptoms at all. On May 30, 1940, a shell dropped close to him in a trench. He estimated that he was about twelve feet away. He remembers a loud explosion, and then he remembers nothing more. His next memory was three or four hours later, and about a quarter of a mile behind the line where this explosion occurred. He was shaking all over, sweating profusely, and, in his own words, "crying like a baby." From that time onward his memory is clear. He thus had suffered an immediate amnesia of three to four hours without retrograde amnesia. He managed to get to a hospital. He had no sign of external injury anywhere, no cut of the scalp and no bruise; but he had a very severe headache, and he was kept in bed for some days. He was very sick and nervous. He slept very badly for the first few nights. Whenever he heard aircraft go past, he was overcome by general trembling, and from time to time he would break down in tears. His thoughts continually were about another soldier for whom he had a particular liking, who had been killed the day before his own incident. He continued to have early morning headaches. He was extremely unhappy. His eyes felt heavy. He continued to sleep badly, and he was still the same about six weeks later when I saw him. He had good intelligence, having reached top grade in primary school at the age of 14. He had had two years in an engineering firm, then joined the regular army, served in Egypt, enjoyed it, and left the regular Army as a reservist and worked in a brewery. He had been married for several years, had two children, and his domestic life was perfectly happy. There was no history of previous breakdown nor of nervous symptoms or epilepsy, nor was there any family history of fits or breakdown. He had never had any illness that he could remember. On examination he had no abnormal physical signs of any kind. X-ray examinations of the skull showed no signs of damage. The cerebrospinal fluid was perfectly normal in all respects. After discussion of his troubles, and particularly his anxieties about his friend who had been killed, he settled down rapidly, and within a fortnight was free from headache, and was cheerful and slept well, and after a month was sent on sick leave. The last we heard of him he was back on duty without symptoms. What was the cause of this

amnesia? Had he been concussed or had he suffered simply an hysterical episode? I have no doubt that he was thrown into an acute emotional reaction by the circumstances of this explosion. His anxiety about his friend possibly predisposed him to this. Are we to call that "shell shock" or not? Is that a mysterious organic reaction of the brain, or is it purely an emotional phenomenon?

Case 2.—The next case was that of an infantry soldier who had been on guard duty when a bomb exploded some ten yards away from him. When he came to the hospital, he gave us a story that he had been unconscious for four days and had from that time onward suffered from severe headaches, from giddiness, whenever he ventured out of the hospital, and from inability to concentrate. He was at times depressed, and he did not sleep well. His personal history was a poor one. He had not attained beyond the third standard grade at school. He had tried all sorts of odd jobs until he had joined the Army, and he had a history of one brother who was committed. He had no history of previous breakdown. He showed no sign of damage to the nervous system or even to the scalp. X-ray examinations of his skull were perfectly normal. The only abnormality was an electroencephalogram which showed many slow waves of the kind found in psychopathic personality. Indeed, he was mildly psychopathic as well as backward. Mental status showed that his memory and judgment were particularly poor. Was this man concussed by the blast of the explosion, or was he suffering from an emotional nervous state like the first one? Eventually I interviewed another soldier who had been with him on guard at the time of the original bomb explosion. I told him I was rather interested to know about the "unconscious" condition of the patient during these supposed four days of unconsciousness, because we had no record from any hospital about this state. The friend said he had heard the patient shouting and ran to where he had been thrown into a heap of soft lime by the force of the explosion, and where he was shouting to be helped out. He was sufficiently conscious to be cursing the lime, knowing perfectly well what it was. It was then clear that this patient had not been really unconscious, and the loss of memory covered a period in which he had been extremely nervous and frightened of further bombings. That amnesia was not the amnesia of true concussion; it was amnesia of hysterical reaction.

These two patients are the only clear-cut examples of which I have kept a case record. But their story is enough to show what sort of reaction occurs in the patient who has not suffered external injury, but who is complaining of nervous symptoms following bombings. In strong contrast with these histories are two others characteristic also of close exposure to bomb and shell explosions but with penetration of the skull by fragments.

Case 3.—A ground engineer was standing on an airdrome near a plane when an aerial bomb exploded ten yards away from him. He stood clinging onto the aircraft, which had caught fire, but he could not speak. He does not remember any pain at the time. He had multiple injuries to his limbs, which were bleeding, and in the course of a few minutes he collapsed, but he did not lose consciousness. He remained conscious but unable to speak until after he was admitted to the hospital about one-half hour later. About six hours later he was semiconscious and almost completely aphasic with a right facial weakness, but no weakness in the limbs. He had extensor plantar responses on both sides and strong neck rigidity. He could understand parts of your conversation with him and simple requests, but he was quite unable to make any reply. The cerebrospinal fluid was blood-stained, under a pressure of 190 mm. After a few more hours he was able to give his name, and the next day he was able to name a match box. He was unable to write his name and he had no apraxia. The cerebrospinal fluid pressure had now increased to 340 mm., and the fluid was still blood-stained. X-ray examinations showed small metallic fragments had entered through a very small opening in the skull and had traversed the ventricles to lodge in the region of the basal ganglia on the left side. They had crossed the cranial cavity, including the body of the ventricles. The scalp wounds received surgical treatment, but

the intracerebral fragments were not disturbed. In three more days he was able to give his name and age; he was a little confused, said the year was 1933, and a little later said the month was June, 1940, which was right. He showed little perseverance in speech. In the course of ten days his speech came back. His right plantar response remained extensor for a few days. His cerebrospinal fluid became yellow and clear within a week after the injury, and he was feeling well. There was a slight trace of right facial weakness in expression but no other sign. He remained well at the end of three weeks, and other wounds in his limbs had healed well. He was allowed a gradual convalescence and eventually went back to duty feeling fit. A letter from him after he went back to duty at an airdrome revealed that at first he did not feel sure of himself, but he soon overcame this.

This patient had been very close to a large explosion, and his symptoms, all except some slight loss of confidence on first return to duty, had all come from contusions by small penetrating fragments which had entered the brain causing aphasia. Any amnesia was exceedingly brief.

CASE 4.—A sergeant in an artillery regiment was in the Metz area of the Maginot Line on the last day of April, 1940, when a shell burst a few yards behind him, throwing him forward. He did not recall the noise of the explosion, but remembered raising himself up from the ground. This was at night. He seemed to see a moving cloud, and for a second he felt unable to move the right arm, where he had sustained a flesh wound; he also found he had been wounded in the left leg. He noticed the right occipital region was beginning to bleed. He walked unaided to a post about twenty yards away. In the post he could see the light of a lamp and no more. His wounds were dressed, and he was sent to a field ambulance unit. He had no headache and his speech was normal. The next day the occipital wound was excised, and a gap in the skull in the occipital region was found with brain protruding through. No exploration of brain was made. He remembers seeing a nurse's cap to the right side of him at this stage. He was transferred to another hospital. He was apathetic, he did not sleep well, and his head wound was bulging but was not infected. He was found to have a complete left hemianopsia. He was receiving sulfapyridine, his temperature was normal, and he could now see faces. On May 22 he could see well to the right but not to the left, and his sight improved gradually. He was reading normally three weeks after the injury. He had no hallucinations. He had a headache for five or ten minutes a day at first, but after three weeks he had none, and he was well except for his hemianopsia. This patient had a large bone fragment in the right occipital lobe. There was here nothing of the condition called "shell shock" in spite of his close relationship to a shell explosion.

Many other histories could be given of severe damage to the brain from close explosion without inducing the phenomenon of "shell shock." In one striking case, a soldier recovered fully with bomb fragments still in his brain, and only after an interval of some two months, under the combined stress of domestic worry and further bombing, he began to complain of the headaches, giddiness, inability to concentrate, and insomnia characteristic of the condition. If we turn to cases of nervous reaction with doubtful head injury from causes other than explosion, we find also that the persisting nervous or emotional reaction bears no relation to the structural damage caused by the injury.

Case histories of patients suffering from "traumatic neurosis" following closed head injuries of other kinds were then given. The development of the posttraumatic syndrome of headache and emotional instability was considered to be related either to reduced *intellectual capacity due to the injury*, or to constitutional predisposition to neurosis. The symptoms in no way differ from those suffering from the effects of bombing. Returning to the condition called "shell shock," we may see in it an emotional reaction to the catastrophe of the

explosion. If actual brain injury has occurred, the syndrome may also appear, and then may be determined in part by the residual cerebral damage. It must not be forgotten that an emotional reaction can occur on a basis of real reduction of intellectual capacity. But the most characteristic case of "shell shock" has no history of direct damage to the brain and no evidence of reduction of intellectual capacity. The condition is essentially one of anxiety neurosis and is best labeled so. The very name "shell shock" predisposes either to self-pity or to self-glorification in the soldier and is a potent factor in perpetuating the condition. The greatest advance in the subject is the abolition of its old name.

The amnesias following bombing are usually patently of hysterical kind. The frequent absence of true concussion leads to investigation of the nature of the amnesia. Experiments were cited to show that true concussion is a traumatic paralysis of nervous tissue caused by acceleration. The change in motion of the head striking a heavy blunt object, or being struck by such an object, is very abrupt. Small penetrating fragments of bombs or shells do not impart such acceleration to the head as a whole and therefore cause little or no concussion. Similarly, the air-borne force of an explosion, though very brief, does not accelerate the head quite as rapidly as a solid mass does, and so does not concuss.

The violence of the displacement of the body and head by an explosion may cause concussion by flinging the patient against some solid object, but there is nothing mysterious or unusual in that. Secondary injuries of skull and spine are common, and fat embolism of the brain from broken bones sometimes occurs. The causes of death from bombing injuries to the nervous system are often complicated. Thus, people may be truly concussed by secondary injuries, and in any case are likely to suffer from the emotional disturbance that we call traumatic anxiety state, traumatic neurosis, or simply anxiety neurosis. Such a psychoneurosis persists usually only in persons with psychoneurotic constitutional liability. It is necessary to assess the nature of the original injury and the degree of intellectual impairment persisting if organic damage to the brain is to be determined accurately. It is naturally of great assistance to have a good record of the original injury. Physicians and surgeons who attend the patient at the time of injury usually lack time to make accurate notes, but any account of the patient's condition when he is first seen is of great assistance afterwards. Amytal is often of assistance in unraveling hysterical amnesias.

With regard to treatment, I might say that most cases of emotional disorder will make a good recovery with persuasion, discussion, and suggestion. In many, some abreaction is essential. In severe cases, usually with bad personal previous history, an extensive investigation of their childhood anxieties is necessary, and in this type of case it is very difficult to get them back to duty involving explosions and bombing again. From the military point of view, the patients who are likely to get back to duty usually do so after quite simple treatment, provided their trouble is understood, provided there is time to go into their story and get down to the nature of their anxieties. They do not react well to faradic or simple suggestion.

Question: What is considered to be the pathology of a concussion? I was taught that in concussion there was some shaking up of the neurons, perhaps some disturbance in the microscopic structure of cells reversible in nature, so that by the time they got to post mortem nothing could be found.

Answer: Most people like to picture some histological change in their minds when they think of concussion. But there is no known histological change. That does not mean that it does not exist, but rather we prefer to describe it as a disturbance in function. Concussion is traumatic paralysis. It is rapidly reversible. It is unlikely that any stain will show such a rapidly reversible change in nerve cells.

Question: Is the incidence of shell shock as great in this conflagration as it was in the last—1914-1918?

Answer: It is very difficult to get any statistical evidence. For one thing, it is listed under anxiety state or traumatic neurosis or brain injury (when such exists). Patients are scattered in numbers of hospitals so that few see many together at any one time, but I should say my impression is that it is just as common as it was in the last war. On the other hand, I am satisfied that the avoidance of the name of "shell shock" and the treatment of the condition as a neurosis has resulted in the reduction of the number of cases with persistent disability to a very small number.

Question: It seems to me that it would be quite difficult in your treatment to gauge how quickly the patients should go back to duty, because if it is a case of concussion, they are liable to need a very prolonged rest before they take up their duty, whereas if it is not a concussion but due to neurotic features, they would get back to duty rather quickly. Is not that a difficult point to decide?

Answer: Yes it is, because it is impossible to lay down a hard-and-fast rule. Each case has to be judged on its own merits. When the patient starts getting up and having headaches, it has to be decided then whether he is attempting too much after a real brain injury, or whether he is becoming nervous. The most important single index of severity of brain injury is the duration of the true amnesia. If retrograde amnesia occurred, the posttraumatic amnesia was a true concussion.

Question: Do you think it is possible to pick a soldier who is not going to have a traumatic neurosis?

Answer: Of all patients who are still suffering from traumatic neurosis more than six weeks after they are injured, the number who have a bad family history or previous history is very high. The proportion with abnormal electroencephalograms is also very high, but they are not always the same group. Some have normal encephalogram and poor family history, and vice versa. Some have neither abnormality. It is unknown how many with equally bad histories fail to become casualties in spite of abnormal stress. That would be an important subject for study.

ALCOHOLISM IN MILITARY SERVICE

MAJOR MERRILL MOORE, M.C., U. S. ARMY

ALCOHOLISM and drug addiction among men in military service are usually concealed and thus are subjects one can approach only indirectly. A direct approach to them is doubly difficult, because it requires consideration of the whole personality of the men in service. Two contrasting extremes come to my mind when I think of the alcohol addict or the drug addict in military service. First is the picture one sees when the band begins to play and the regiment is out on dress parade. No one would think to see the stalwarts marching past the grandstand that there could be one drunkard in the entire outfit. The other picture is the one that the psychiatrist sees years later in the hospitals of the Veterans' Administration. As you know, many patients are admitted there on account of alcoholism or drug addiction. Somewhere between the parade ground and the Veterans' Hospital, alcoholism and drug addiction become a problem.

A considerable number of the patients admitted to Veterans' Hospitals are ex-service men whose illness has been diagnosed *alcoholic psychosis*. A smaller number of men are given either the diagnosis *psychosis due to drugs and other exogenous toxins* or *without psychosis, drug addiction*. The early stages of these conditions may not be obvious when men are in camp or on maneuvers, nor are they a prominent feature among the neuropsychiatric conditions encountered in actual combat. But, when the war is over and men are depending on their service record for hospitalization, a substantial number of cases of alcoholism or drug addiction will crop up expecting care for the rest of their lives. How did these men get into the service, assuming that they brought their problems with them, or how did their problems develop in service? How is it legally possible for them to claim service conditioning or service precipitation of their difficulties that arose afterwards?

First, one may consider the men who are already addicted to the excessive use of alcohol or drugs *before* they enter the Army. In the first World War men were taken into military service very rapidly. If they had a neuropsychiatric examination, it was often rather sketchy. Some might say that is still true. But neuropsychiatric entrance examinations are more complete today than they were twenty-five years ago, although sometimes a neuropsychiatrist still has only a very few hours in which to examine twenty or thirty applicants for military service. In doing this work, anyone can make a mistake, and when one is in a hurry, it is easier than usual. To prevent this, the time allowed for the examination of each case should be longer, and the form of the examination should be amplified.

Reprinted from The Military Surgeon 91: 29 (July), 1942.

Even though the examination may comply with the strict limits of the military forms that are filled out, it is still possible for a good many alcoholics to get into military service. There is no exact way of preventing this at the present time. Theoretically, the alcoholic is not good material, but occasionally one makes an adequate soldier. But too many alcoholics are not good for the Army, the General Grant tradition to the contrary notwithstanding. I wish someone would decide whether or not the Army is good for the alcoholic. It may be possible that some of the factors which have precipitated alcoholism in an individual case may be alleviated by military life. On the other hand, military routine may aggravate the alcoholic tendencies of some individuals. The Army, of course, is primarily a functioning defensive or offensive unit, and hence can concern itself only secondarily (if at all) with the therapeutic advantages of Army life for the individual. But, since the Army is made up of groups of individuals, their welfare in Army life becomes an essential part of the mechanics of the Army. The benefits a man gets from Army life depend on his own personality, the nature of his work, the way he is handled by his superior officers, and the vicissitudes of military life.

Today when men are being examined for the Army, there is a careful checking of outside sources in an effort to obtain some information about the man's personality and habits. The problem still remains, "How can the alcoholics be excluded from service?" In some cases a careful neurological or psychiatric examination gives little evidence of latent alcoholism, because if the alcoholic individual eats and exercises adequately, he may not show the physical effects of heavy drinking. Even if the examining officers communicate with the parents, the teacher, the minister, or the postmaster, a prejudiced opinion may be returned in favor of the man, especially if the family wants to get rid of him, or if he wants very much to get in the Army and they feel that enlisting is the only way out or is the best way to save his face in the community. These attitudes aggravate the situation and work to the detriment of the government. Many people tend to feel that if a man does not fit in anywhere else, he can enlist in the Marine Corps or go into the Army or the Navy, and that then he will be Uncle Sam's problem. Certainly he will then no longer be the problem of his own family or the out-patient clinic or the social service department of a hospital. People have come to me as a private physician to ask me to give favorable recommendations to selective service boards concerning ne'er-do-wells, latent or patent alcoholics, and various types of psychopaths who, in all probability, would adjust themselves no better in the Army than they have done in civilian life. I am sure that many other physicians in the United States have had similar requests. The public must learn that the qualifications for success in the Army are essentially the same as those in any other profession. Stable and mature persons are needed. It may be a fact that during the Napoleonic wars just anybody was good enough for the Army and was welcomed there, the fellow who got a girl in trouble and had to leave town, the poacher avoiding jail, and the criminal who did not dare show up again at home. Those men made a motley gang that was good enough for Boney, but that is no longer true today. Our Army is reorganized. It is streamlined. It is scientific, and it is psychological. *It wants and it must have the best.* A military life is not good shotgun

therapy, and the Army, Navy, and Marines do not want psychopaths, alcoholics, and neurotics, or persons with behavior difficulties. It is going to take some time before these points can be made clear to the public, but if that can be done, and if the present standards of admission can be rigidly enforced, twenty years from now there may be fewer derelicts suffering from the end results of chronic alcoholism and drug addiction in the Veterans' Hospitals of 1962.

When I speak of alcoholism in the service, I do not mean the kind of drinking seen when the American Legion is in town. That is something different. I would distinguish that as being a healthy kind of "blowing off steam," something that does not occur very often. In fact, it occurs only during the Legion Conventions. I realize that when the Legionnaires meet annually their emotions are very strongly stirred by convening and the recollection of old times. Generally speaking, the Legionnaires are not the type one would define as alcoholic.

The alcoholic has been variously described as a man who cannot get along with liquor and who cannot get along without it, or, he is a man who lets liquor run him rather than controlling his liquor. The alcoholic is a person in whom alcohol acts as a poison; he does not react to alcohol (physiologically) as a normal man reacts. He is a person who drinks to a degree that interferes with his work and home life. A final definition of an alcoholic is one who cannot stop drinking. These are all practical definitions; they are not scientific, but a jury would know what is meant by them and would understand the thread of common meaning that connects them all. We must use such definitions as these until more basically scientific facts are discovered. If an underlying basis for a definition can be found, it will probably contain some of these central ideas.

The problem of alcoholic addiction in military life is a good deal like the problem of alcoholism in business. If you ask a business man if alcoholism is a problem in his firm, he will say, "Certainly not. As soon as a man starts to drink, we fire him." But, if you say, "How many men have you fired during the last ten years for alcoholism?" he may be able to locate in his records a fairly large number.

In general, when alcoholism occurs in the Army, the drunk gets put into the guardhouse and is punished or discharged. The handling of him depends on the way the men live and on his rank, as well as upon other personal factors. If an officer becomes alcoholic, usually his friends take care of him, or he may be put at a post where he is not too important. Or he may not be advanced, or he may be retired prematurely. This occurs through the internal mechanics of military administration. In some instances, however, when alcoholism is acute, the individual is put into a hospital for observation and treatment. Alcoholism is accepted as one of the drawbacks inevitable in an imperfect world. However, some consider that excessive drinking in the ranks is an index of poor material or low morale, and that the best possible way to prevent poor material from getting into the service is by rigid entrance examinations and by scrupulous following up of the qualifications for admission to service that are already in operation. This applies to officers as well as to enlisted men.

Excessive drinking among enlisted men creates several difficult problems. These problems are not simply administrative or merely medical, they are basically psychiatric in their nature. Recently, I heard an officer discussing this

matter. He said, "Yes, heavy drinking among soldiers is a problem, particularly when you have large numbers of men who are not actively occupied most of the time. Under certain unfavorable conditions, it can become serious, but a lot can be done in a constructive way to control it. Where there are few troops it is usually not much of a problem. In general, it can best be handled in the following manner: First of all, military police are put on and the penalties for drunkenness are increased. Second, arrangements are made to give the enlisted men the use of facilities for recreation and diversion, such as swimming pools, tennis courts, bowling alleys, etc., through clubs and social groups; and dances, parties, and picnics are planned. We found that the more we saw to it that the fellows had a fairly good time, the less difficulty they had with the sort of desperate and destructive drinking that military men sometimes go in for." He added, "It ended with our enlisted personnel having better opportunities for recreation than the officers had, but the officers didn't object, because they thought the results were worth it. On the whole, it was a very good solution. Of course, it would be different under conditions of actual warfare."

Other officers who are familiar with disciplinary and recreational problems in military service corroborate this point of view.

In general, the men who cannot adjust themselves in military life and who succumb to excessive drinking are probably the same kind of inadequate individuals for whom some assistance and supervision have to be devised in civil life. And often the type of help needed by inadequate and alcoholic individuals in their efforts toward emotional and social adjustments are more than the ordinary civilian or military community alone can afford.

In the first World War these problems were beginning to be recognized. Now recognition is more widespread, and more of an attempt is being made to deal with them today than was made in 1917. The first emphasis is now being put on preventive measures. Yet, a satisfactory approach to these issues remains a partially unsolved problem in military life. When the first World War began, in April, 1917, there was no question about where things were heading. There had to be an all-out preparation for action, and the nation fell into a frenzy of the most patriotic and strenuous military effort this country had ever known. After a relatively short period of training, men were shipped immediately abroad and action was quickly forthcoming. All was excitement and activity. The problem of undrained emotional energy among the troops was not so severe as it has been until the declaration of the present war. Now we are really in a shooting war with a large and growing Army. The general staff is so busy equipping and training men at this moment that it cannot be expected to look after the individual emotional problems of service men. At the moment, this is a civil problem and has to be handled by communities, not only through the U.S.O., but through every community organization. Great progress has been made in the last six months along these lines. Until war has been actually declared, in some communities men in uniform are discounted socially. After the declaration of war, however, their stock goes up as war tension rises and the public begins to appreciate soldiers and sailors. Civilians in any community, with relatively slight effort, can do a great deal to turn the interest

of enlisted men *away* from the inadequate and destructive types of amusement and drinking that men in uniform sometimes fall into when they are on leave or liberty. Until such effort is made by civilians and community organizations to provide normal entertainment, excessive social drinking is apt to continue. The alcohol problem in military service is essentially an emotional or personality problem, just as it is in the civilian life, though it is also directly related to the release of unspent energy, in recreations and diversions carried out by individuals or groups in sports, games, dancing, and all social activities. Although social measures do not get at the roots of the alcohol problem, I believe that 95 per cent of the men who drink too much while on leave, for example, would accept nonalcoholic entertainment just as easily. For that matter, alcoholic entertainment (in moderation) in a wholesome setting would be much better for them than drinking alone. Not alcohol, but the intemperate use of alcohol, is the problem in the army as well as in civilian life. People have asked whether or not beer should be sold near military posts. I, for one, think emphatically that beer should be sold and that drinking in moderation should be encouraged. Recreational facilities of all sorts are essential to men undergoing the strain of preparation for military life. Of course, someone will point out that this brings up the sex problem, but the United States Public Health Service is learning how to handle this quite adequately. In spite of progress, we shall always have with us the sporadic critic or the fanatic who will complain if a soldier off duty has a ten-cent beer or puts a nickel in a juke box.

One of the most important aspects of Army life is the relationship between the officers and men. I believe that one of the most effective approaches which a professional man can make to any situation is the psychotherapeutic or melioristic approach. This can be used whether one is a doctor, a lawyer, or an officer. This approach aims at establishing confidence between individuals and encourages the best possible outcome of the situation. This point of view is well-known to physicians in their work with neurotic and psychotic individuals. It has found a concrete expression in the mental hygiene movement, which consolidates the psychological findings of psychiatrists, physicians, social workers, and lawyers. This information is now available in a form that can be applied in the home, the school, and the community. There is no reason why some of the basic principles of mental hygiene should not also be applied in military life. Men learn a great deal from military service that they could not learn at home or in school or in the community where they have lived. A military program can and should include constructive outlets for the energy of the soldiers to balance the necessarily destructive aims of warfare. There is no reason why along with their other duties officers should not understand and use the principles of mental hygiene in their work. Essentially that is exactly what a good officer does. If a soldier looks back through his military experience, he will remember some officers who were outstandingly capable, constructive, realistic, and fair, and were a good influence generally on the men under them. In military life, as in civilian life, the influence of the superior personality is a very powerful force in molding morale and directing policy.

The problem of draining emotional energy for many soldiers is *not* completely taken care of by physical work and military drill. There are a great

many men who drill all day, fall out, turn in, and that is all there is to it. But there are also in service men who have a superabundance of energy. Work does not exhaust them. Furthermore, there is a mischievous type, who seems compelled to go out and have some adventure once in a while, to get into trouble or get drunk, or do something exciting. Even he is not basically the alcoholic type. The soldier who occasionally gets drunk and gets over it is not the one I mean when I speak of the alcoholic.

I believe the alcoholic is distinctly a sick person, a man with a sick or abnormal personality. His personality is far more unstable and more immature than the average. He stands out as distinctly different from his fellows. He may be the kind of maladjusted service man who is chronically complaining, who tends to blame others, who "can't take it," and he may show what the psychiatrist calls "paranoid tendencies." There are a few crazy people in the Army who get along perfectly well. They fight and go through campaigns; occasionally one may become a hero. But there is also the kind of person who never gets along anywhere very well. We have to fall back on that overworked word *psychopath* to describe him. The alcoholic and the drug addict are recruited from the ranks of the psychopaths. We have said that alcoholism is an illness; it may also be considered the symptom of an illness. By that I mean that alcoholism is a disturbance, a smoke screen, covering an underlying personality disturbance. To call it a disease is merely a simple way to acquaint people with the fact that we realize the alcoholic is a sick person.

If you study an individual alcoholic, it will be apparent his symptoms go back to his early life. I should like to tell you about one patient with whose case I am familiar. He is a man who has been committed now for about twelve years to a Veterans' Hospital. I am using his case as an example, because it illustrates several important points. The patient is now 49 years old. First his illness was diagnosed *alcoholic psychosis*, but after he had been in the hospital for a few years the diagnosis was changed to *dementia praecox, paranoid type*. He was born in New England and was an only child, whose father died when he was four. He graduated from college with high marks and was engaged once, but his fiancée jilted him. He served abroad with the Army of Occupation. He always drank a great deal and became drunk frequently, but he managed to get by because his friends covered up for him very well. He was known to have drunk to excess on several occasions before he was discharged. Once he was called before a neuropsychiatric examining board (shortly before his discharge), at which time a psychiatrist saw him and made a note in his record that the patient had a psychopathic personality with paranoid tendencies. After discharge from the Army he went back to work but did not get along very well. He began to drink excessively and got into several brawls. About 1925 he began to develop the idea that he had invented an electric machine that would do anything. Then he began to feel that people were trying to steal it and that he was being persecuted. Following this, he was committed to a private hospital for a period of study. At this time, the clinical picture was complicated by his drinking and by neuritis and other symptoms due to drugs he had been taking. This cleared up and he was released. Later he got into the same kind of trouble

again, and this time was committed to the Veterans' Hospital. When I spoke with his mother about him, she said that he was very sensitive as a little boy. He was overidealistic, perfectionistic, and he did not get along well with children his own age. He did get along very well with older people. She said he was always timid and that he was afraid of men, and he was also very reserved with girls. She could not get him to go to dancing school. He had a good deal of trouble with bed-wetting until he was 8 years old, and after that masturbation was a severe problem. Once she took him to see a child psychologist on that account. When he went to college, the school authorities reported that he was one of the men who was always drunk at any dance or social gathering. He would often get so drunk before a party that he would not even get to it. He would occasionally take a girl to a dance, where he would get drunk or start a fight, and somebody else would have to take the girl home. He was seclusive and not very popular socially. Out of a class of 100 men, he had only one close friend, who also drank heavily. His military service record was not remarkable. After the war he developed a frank psychosis.

I have taken as an illustration a man who started out with alcoholism and developed a definite psychosis. Looking back, I do not think anyone at the beginning could have said that this man was normal or that he was well. He was a problem child, a difficult adolescent with many neurotic traits, and probably had a deep-seated neurosis, which slowly developed, with social deterioration, finally resulting in the complete breakdown of the individual. Whether alcohol was the cause of the breakdown we do not know, but it was an important precipitating factor. Alcoholism combined with paranoia is usually a precursor of permanent mental illness, as turned out to be the case in this instance. This man has not responded to any of the efforts made to treat him. He turns his back on anyone who comes near him. He never speaks but just closes his mouth and sits. Occasionally he is violent and combative.

The results of attempts to treat the chronic alcoholic addict have not been very encouraging. The different forms of shock treatment have been tried without much effect. It is very difficult to say just what the alcoholic is or how he can best be approached for treatment. Usually the alcoholic individual may be classified with the psychopathic or the borderline group, though in some instances excessive drinking is a symptom of an actual psychosis. Many alcoholics for a long time appear to be neurotic individuals going through severe conflicts. They drink to escape their conflicts and the resultant nervous tension.

When a man drinks, the physiological and pharmacological effects of alcohol are very definite. First, alcohol enters the blood stream very rapidly through the stomach wall. Some of the alcohol is stored in the liver. It is believed that this fact may partially explain why some people can hold their liquor and others cannot. Tolerance may be an expression of liver function. For many years, Dr. Timothy Leary, at the Boston City Hospital, has studied cirrhosis of the liver in cases of chronic alcoholism, where it is a very common finding. He reports that the subject needs further study. One confusing point is that cirrhosis of the liver is sometimes found in persons who have never touched alcohol.

Next, alcohol passes into the spinal fluid by which it comes directly in contact with the nerve cells. Once it was believed that a man who had a certain

amount of alcohol in his blood was drunk, and if he had more, he was more drunk. This, of course, is true within general limits, but more careful study of alcoholic individuals has recently shown that one can take a drink and begin to get "tight" at a certain blood alcohol level. Then, when the blood alcohol level, after further drinking, rises, instead of getting more drunk, the individual seems to adjust himself to it mentally and may appear more sober. These observations need to be explained. Learning phenomena is not sufficient; there may be something more, something physiological to this reaction. These findings may limit the value that up to now has been found in "drunk meters" and alcohol breath tests, but this should not entirely destroy their use. Legally, blood and breath alcohol tests are still valid, subject to interpretations, and they are far better than nothing.

Different tissues, such as muscle and brain, apparently oxidize alcohol at slightly different rates. For example, a laborer may get over a drunk quicker than a brain worker, because he may burn it up in physical exercise out-of-doors. Furthermore, the oxidation rate of alcohol in the body may be somewhat altered by certain drugs, for example, dinitrophenol derivatives, and possibly benzedrine, though the evidence is not final. It is possible that some day a drug may be found that will alter the oxidation rate of alcohol in the human body in a way that may be therapeutically useful, though at present the available drugs are too toxic for therapeutic use. The factors that influence the lowering of the blood and spinal fluid alcohol content are all-important physiologically and need to be studied much more intensively. Generally speaking, the blood alcohol level in an individual is the result of two factors, the amount of alcohol taken in and the body weight, since alcohol is dissolved in all body tissues about equally. For example, if you take two men, one who weighs 250 lbs. and another who weighs 125 lbs., and give them the same amount of alcohol, the man who weighs 125 lbs. will have a blood alcohol level about twice as high as that of the man who weighs 250 lbs.

The next point to mention, when speaking about the effects of alcohol, is this: There is no evidence that alcohol increases human efficiency, except possibly momentarily. As the blood alcohol level rises, efficiency of the nervous system and performance gradually are reduced. From elation, drinking can lead to coma. Although we speak of getting "tight," we really get "loose" when we drink, because the basic action of alcohol as a narcotic drug is to depress the higher centers and release the inhibitions. There is a vast amount of misinformation about that one point. Forty or fifty years ago, physicians were taught that alcohol was a stimulant, and it is often listed among stimulants in old textbooks. Actually, alcohol acts as a depressant in its effect on the nervous system; the only stimulation alcohol affords is to the taste buds of the tongue and the mucous membrane of the throat.

From the point of view of military efficiency, this is significant. Many years ago alcohol had a very important part in the military diet. It has been served as grog in the Navy. Rum rations were given to Continental soldiers. Sam Houston is said to have fought most of his Mexican campaign on rum, and at the Battle of New Orleans it is said that Andrew Jackson was so weak (after a

strenuous march) he had to be helped up on his horse at first, and that before he could lead his men, his attendants gave him a mug of whiskey to drink. But the best information about the modern Army is that alcoohl plays no official role in warfare and is excluded from actual maneuvers. It has been reported, for instance, that the Nazi troops in active campaigning are not allowed any alcoholic liquor in any form, and that the picked troops who invaded France in May of 1940 were, for the most part, men who had been on a military training regime more strict than that of any football teams in our better universities. If this is true, it may be very significant. It may mean for all armies now that under serious military conditions the amount of drinking that is permitted may be greatly restricted or practically nil.

In summary, however, man's nature is not apt to be basically changed, even by warfare. In whatever form alcohol may be provided or available as a beverage, and whatever its effect may be, considered from the realistic point of view, it is present and is accepted as a part of life, along with food and drink, and the fact remains that for the great majority of the civil and the military population, alcohol does not constitute a problem of serious importance. The individual with alcoholic tendencies is the exception rather than the rule. What is important, however, is that drinking in moderation be encouraged or emphasized. Personal repressive and restrictive measures are basically of little use, since they fail to get at the roots of the problem. It is also important that reasonable and wholesome facilities for relaxation and recreation be provided men in military life. And, what is most important, that further effort be made to discover and understand the type of individual who is inadequate, who tends to drink to excess in the escapist, addictive, or destructive patterns, and to keep him out of the armed forces of the nation. He will still exist, of course, and will still remain a problem for the community to deal with, but his future is not as hopeless as it once was now that physicians are more clearly realizing that the alcoholic is a sick person and that he was sick *before* he began to drink, and that he is sick between bouts when he is *not drinking*. His illness can be further defined as a deep-seated disturbance in his personality, a long-standing difficulty, a maladjustment in his emotional or in his social life, sometimes the expression of an inner problem, or sometimes the result of an external situation in his life. In this sense, alcoholism can be regarded as a symptom, or as a smoke screen, for that is what it always turns out to be, when the individual is studied and an effort is made to treat him. About this basic disturbance of which alcoholism is the symptom, physicians know as little today as was known about diabetes forty years ago. By analogy, it is as important to keep out alcoholics of the armed forces, generally speaking, as it is to keep out diabetics. That is what physicians and neuropsychiatrists at the present time are trying to do. To some extent they are successful at this task, and to the extent that they are, there will be just that many *less* alcoholic derelicts and drug addicts to be cared for in government hospitals in the future. The men who are excluded, however, will probably remain in the community and will probably continue on a destructive or disintegrative path, as disturbed individuals without treatment usually do, but even there they are not being ignored. An effort is now being made in some

communities to study and treat these individuals with the aim of preventing alcoholism. This effort is based on the idea that they are sick, and that their sickness is accessible by three well-known avenues: chemical, psychological, and social. It is believed by those who are carrying on this work that the methods of science and a modern progressive and humanistic approach will not fail in time to produce worth-while results in terms of more satisfaction and usefulness for the alcoholic, and the reduction of unnecessary psychic suffering on the part of the alcoholic individual and those who are dependent on him.

AN ACUTE RESPIRATORY INFECTION RESEMBLING SO-CALLED ACUTE PNEUMONITIS*

A Report of 40 Cases

Lieut. Com. LeRoy B. Duggan, M.C., U.S.N.R., and
Lieut. William L. Powers, M.C., U.S.N.R.

During the months of June, July, and August of 1941, the department of medicine at the United States Naval Hospital, Corpus Christi, Tex., observed an acute infectious disease of the respiratory tract with unusual pathological changes in the lung.

There were 112 admissions with acute respiratory infections during this period, and the present study is based on 40 cases with the above unusual lung findings. These patients were young adult members of the United States naval military service and were between the ages of 17 and 26 years.

Cases which apparently simulate these have been reported during the past several years in the United States and foreign countries, e.g., England, France, Hawaii, and Spain.

The disease differs from the familiar forms of lobar pneumonia caused by pneumococci and from the usual types of bronchopneumonia caused by hemolytic streptococci, staphylococci, and other organisms. In the majority of the cases reported the course of the infection is characterized by an insidious onset with minimal respiratory and mild constitutional symptoms. At the onset there are no definite abnormal physical signs and the leucocyte count is normal or only slightly elevated. Within 48 hours a roentgenogram of the chest shows a small area of pulmonary consolidation usually located at the base of one lung.

This disease has been described by a variety of names, e.g., as acute influenzal pneumonitis,[3] acute pneumonitis,[1] atypical pneumonia,[5] acute interstitial pneumonitis, atypical bronchopneumonia,[11] peribronchial pneumonitis,[9] and adolescent pneumonia.[6]

In 1934 Gallagher reported a series of 16 cases with what he termed adolescent pneumonia and which had many characteristics very similar to this clinical picture. Bowen, however, was apparently the first to suggest that this infection might be a new disease entity when, in 1935, he described an outbreak

*Reprinted from the U. S. Nav. Med. Bull. 40: 651 (July), 1942.

occurring among Army troops stationed in Hawaii. In 1936 Allen, at Fort Sam Houston, Tex., reported a series of 50 cases with acute pneumonitis. In 1937 Scadding, in England, reported a group which he called disseminated focal pneumonia. In 1938, 1939, and 1940, sporadic cases and minor epidemics were reported in the United States and England. These outbreaks were widely scattered in this country, with isolated cases and minor epidemics being reported in Pennsylvania, Oregon, Texas, New York, Minnesota, Ohio, Delaware, Maryland, California, and Massachusetts. In 1941 small epidemics were reported from widely separated points in Texas and Oklahoma.

The majority of these reports describe cases very similar to those we have observed in our series. However, those described independently by Cass in 1936 and Reimann in 1938 had more marked constitutional symptoms than those we have seen. Also the series reported by Reimann and Haven in 1939 differed in that those cases associated with abnormal pulmonary changes had severe constitutional symptoms and those having mild symptoms similar to our cases had inflammatory changes in the upper respiratory tract. Symptoms due primarily to inflammation in the upper respiratory tract were not an important or frequent finding in our cases or in the majority of those reported by other workers.

At the present time there is considerable speculation as to whether these cases represent a separate disease entity caused by some type of filtrable virus or are simply atypical bronchopneumonias caused by one of the usual types of bacterial organisms. Since these cases occur largely in previously healthy young adults, Lyght and Cole have questioned not only that this infection is typical for this age group and type of individual, but also that it is a new or separate disease entity. They call attention to the fact that the concept of pneumonia, as a disease entity, can no longer be restricted to a well-defined clinical picture because both the nature and severity of the infection are subject to too many variables. It was their opinion that the concept of pneumonia should be broadened to include the type of case under discussion.

Although the etiology of this disease is still in doubt, the prevailing opinion seems to be that it is caused by some type of filtrable virus. There is some evidence to support this view as shown by the following, e.g.:

1. The contagiousness of the disease.
2. The inability to demonstrate reactions associated with any known pathogenic bacteria either by culture of the sputum and blood or by other laboratory procedures.
3. Failure of the infection to respond favorably to sulfonamide chemotherapy.
4. Work of Horsfall and Weir and Stokes and Francis with recovery of a virus and production of pulmonary consolidation in animals.

Stokes and Francis obtained an unusual virus from the nasopharyngeal washings of one of Reimann's patients and from the blood of another. It was virulent for mice and caused pneumonia and encephalitis about 2 weeks after inoculation. However, they were unable to do serological tests because of the loss of the agent and, therefore, were unable to establish a causative relationship.

Although Horsfall and Weir were not able to infect a variety of animals by intranasal inoculation with throat washings from a number of clinically typical cases, they were successful in transmitting the infection to the wild mongoose. They succeeded in recovering a virus which on inoculation pro-

duced pulmonary consolidation in the animal. Healthy mongooses placed in contact with infected mongooses developed pulmonary consolidation. The virus was neutralized by the serum of mongooses convalescent from the infection but was not neutralized by normal mongoose serum. Serum of human beings convalescent from acute pneumonitis also neutralized the virus, but serum obtained from the same persons during the acute phase of the disease failed to do so. The virus was filtrable through Berkefeld V. and N. Candles, was not inactivated by glycerin or freezing and drying in vacuum, and was propagated for at least 30 serial passages on the chorio-allantoic membrane of the developing chick embryo. It was the opinion of the authors that virus is the cause of so-called acute pneumonitis in human beings.

Enders, Sullivan, Hammon, and Meakins of the Department of Bacteriology, Harvard Medical School, attempted to demonstrate an etiologic agent by the inoculation of mice, rabbits, guinea pigs, ferrets and macao mulatta with blood, sputum, and nasopharyngeal washings from 11 patients in Murray's series of cases, but were unable to produce any recognizable pathologic changes in any of the animals.

The pathology of this disease is limited to the findings in one fatal case which occurred in Kneeland and Smetana's series at the Presbyterian Hospital, New York City. The microscopic features of the pneumonia were characterized by a mononuclear cell exudate in the pulmonary alveoli and an acute pulmonary vasculitis. However, none of our cases are comparable to their group of severe infections in which the death occurred, and therefore, any conclusions drawn regarding similar pathologic changes in our series of cases are likely not to be accurate.

Most of the reports of this disease have been made as a result of the study of outbreaks occurring among young adults living either in colleges or quartered with military troop concentrations. In these two groups a substantial number of cases have occurred over relatively short periods of time, and therefore, the disease has been thought to be readily transmissible. Although our report represents a similar situation, we were unable to find that the disease was any more prevalent among the men living in barracks with possible contacts than in those who were unexposed.

The disease occurred in about the same ratio in aviation cadets, was of about the same severity, and ran a similar clinical course. Enlisted men living at outlying auxiliary fields acquired the infection, but these cases were rare. Although we were unable to trace exposure or contacts of sufficient number to determine the definite degree of contagiousness, it was our opinion that it was probably transmitted from one person to another by casual contact.

There was no evidence to indicate that lack of physical fitness, previous upper respiratory infections, abnormal exposure, physical fatigue and climatic conditions were predisposing factors.

CLINICAL DATA

The average typical case began as a simple acute infection with minimal respiratory symptoms. Usually for a day or two preceding admission, the patient had not felt well. Following this, he developed a moderately severe

frontal headache, backache, pains in legs, weakness, unproductive cough, and fever (100°-102°). In the large majority of instances, these patients were considered only moderately ill.

On admission, physical signs were minimal or entirely absent. Usually there was slight redness and injection of the pharynx, and an elevated temperature. The pulse was either normal, or the pulse-temperature ratio showed a relative bradycardia. The respiratory rate was normal. There were no abnormal physical signs on examination of the chest. The leucocyte count was normal or slightly elevated with the percentage of polymorphonuclear cells either normal or slightly increased.

The diagnosis was usually made on the third to fifth day when roentgenogram of the chest was made and a small abnormal area of moderate density was found in one lung field. A day or two later crepitant râles could be heard at the base of one lung, posteriorly. Usually there were no physical signs indicating pulmonary consolidation. The cough continued and by then the patient had begun to expectorate a small amount of mucopurulent sputum. The temperature returned to normal in about 6 to 8 days. Defervescence was by slow lysis. By this time medium moist râles could be heard at the base of one lung and usually persisted for 7 to 10 days. The patient remained in the hospital another week or two and was returned to duty well.

ANALYSIS OF SIGNS AND SYMPTOMS

Approximately one-fourth of our cases had a relatively sudden onset, under 24 hours. Only one-sixth had a previous history of an upper respiratory infection, such as colds and sore throats, during the 3 weeks preceding the onset. Approximately one-third had typical nasal symptoms of an acute rhinitis at the onset of the infection; one-fourth had a mild sore throat. Only two patients had an actual chill and only three complained of a chilly sensation. One-fourth complained of substernal discomfort which was usually a burning sensation, although a few complained of substernal tightness. There was no actual chest pain characteristic of pleurisy; no dyspnea or the expectoration of bloody sputum.

The physical examination at the onset was characterized by its lack of abnormal findings. In approximately three-fourths of the cases the chest was normal. In eight cases there were crepitant râles at the bases of the lungs, but most of these reported to the sick bay after having been sick for a few days. In a few cases sibilant râles were present and in about the same number sibilant and crepitant râles were both heard. These were usually located at the base of the lungs, posteriorly. Diminished breath sounds were present in a few cases and dullness on percussion in only one. There were no definite physical signs of pulmonary consolidation in any case at the onset of the infection.

The temperature curve varied moderately during the course of the disease. In the majority of the cases the temperature would rise to 101°-102° at the onset, remain elevated for 4 to 8 days, dropping gradually to normal. In about one-sixth of the cases the temperature was elevated to 103°-104° for several days. These patients were definitely sicker than the others, as manifested by

associated clinical evidence. In five cases there was a low-grade fever under 100° which ran from 12 to 23 days. The pulse temperature ratio was either normal or a relative bradycardia was present.

During the course of the illness the two most significant factors were the paucity of chest findings on physical examination and the persistence of râles once they appeared. In five cases râles were heard before the third day, but in these we were doubtful as to whether the history of the day of onset was accurate. In the large majority of cases râles were heard first from the fourth to the eighth day of the illness. In one-fourth of the cases no abnormal chest signs were ever apparent and in four cases râles were not heard until the ninth to the eleventh day. The râles were usually medium, moist in type, and usually persisted from 1 to 2 weeks.

In the large majority of cases the sputum was usually absent or very scanty for the first 4 or 5 days, and after that the patient expectorated small amounts of mucopurulent material for a few days.

Approximately one-half the patients were in the hospital for 3 weeks and the majority of the remaining were in about 2 weeks. A few cases were sent to duty in 8 to 10 days; these were very mild cases. In the majority of cases hospitalization was prolonged by the weakness of the patient, a persistent cough or râles after all other symptoms and signs had subsided. The complete recovery of the patient was essential in our cases because of the necessity that he be fit for any and all military duty before being allowed to leave the hospital.

There were no serious complications in any of our cases and no fatalities.

ROENTGENOLOGICAL DATA

The outstanding observation concerning the roentgenographic findings was the fact that changes within the lung were present for several days before they could be determined by physical examination of the chest. Three of our cases had roentgenograms as early as the second day, and changes were found in all of these. In Murray's series of cases changes were found within 24 hours after the initial symptoms.

The roentgenograms usually showed a small irregular or rounded area of soft to moderate homogeneous density in the central portion with borders shading into normal lung. In many of the cases the density was very thin, although of an even quality. This was particularly true of those lesions appearing in the costophrenic angle. As a whole, the lesions were not extensive, particularly those extending from the lower border of the hilus and those found in the costophrenic angle. It was our opinion that some of the lesions extending below and outside the left border of the heart would have been shown to be more extensive could we have obtained lateral roentgenograms of the chest. The distribution of the lesion was lobular rather than lobar and the majority showed only a small section of one lobe to be involved. In a few cases the lesion was more extensive, but these were the exception rather than the rule. Multiple, successive roentgenograms in several cases demonstrated that as the disease progressed the density increased, became more sharply defined and frequently increased in size. Also, resolution was shown to follow the course of other types of pneumonia, the density gradually diminishing and becoming more mottled and linear in type.

In the majority of cases, approximately three-fourths, the lesion either extended from the lower border of the hilus region into the cardiophrenic angle, or appeared either in the costophrenic angle or at the base of the lower lobe of the lung. Sixteen cases had lesions at the left base, 7 at the right base, and 5 at both bases. Seven cases extended from the hilus toward the mid-portion of the lung. In 4 cases the lesion occurred in the upper lobe, and in 2 cases there were lesions in both upper lobes. In 1 case, lesions were located in the right upper and lower left lobes.

LABORATORY DATA

The average case showed a normal or slightly elevated initial leucocyte count and a normal to slightly elevated percentage of polymorphonuclear cells. Only 2 leucocyte counts were below 6,000 and the majority ranged between 6,000 and 9,000; 6 counts were above 10,000, but a few of these were obtained late in the disease.

Because of several factors inevitably concomitant with the commissioning of a new hospital, we were unable to carry out extensive bacteriological studies. We were unable to inoculate any animals with either the blood, sputum, or nasopharyngeal washings of any of our patients. In one-sixth of the cases we examined the sputum for tubercle bacilli and the predominating type of organism. Tubercle bacilli were not found in any specimen examined. Staphylococci, streptococci, pneumococci and Micrococcus catarrhalis were the predominant organisms found. When pneumococci were found present, we attempted to determine the type but were unable to do so except for one case which was pneumococcus type IX. The sedimentation rate was moderately elevated in the large majority of cases.

TREATMENT

The treatment was largely symptomatic with the emphasis on rest, supportive measures, and sedatives for cough and restlessness. In 12 cases sulfathiazole was administered with 30 to 90 grains given initially and 15 grains thereafter every 4 hours night and day.

We were definitely convinced that the drug was not as effective in this group as in the usual pneumococcic infections, and there was considerable question as to whether it had any beneficial effects.

SUMMARY

A series of 40 cases of an acute infectious disease of the respiratory tract with unusual pathologic changes in the lung have been described and analyzed. In general, our cases closely resemble those described as some type of pneumonitis by workers in the United States and abroad.

The majority of the cases in this series began as a simple acute infection with minimal respiratory and constitutional symptoms: a normal or slightly elevated leucocyte count and no abnormal physical signs. The diagnosis was usually made by means of the roentgenogram and *in the large majority of cases could not be made by any other means.* It usually showed a small area of increased density most often located at the base or hilus of one lung. Abnor-

mal physical signs in the lungs, usually manifested by crepitant râles, were not apparent until the peak of the severity of the disease had passed. Although the constitutional symptoms were not severe, a prolonged period of convalescence was usually required because of the weakness of the patient.

The pathology and etiology of this disease are still undetermined, although there is some evidence to indicate that it is caused by a filtrable virus.

The disease is apparently contagious, but only mildly so, and is probably transmitted by casual contact.

Lack of physical fitness, previous upper respiratory infections, abnormal exposure, or physical fatigue were not predisposing factors.

The disease did not respond favorably to the action of sulfonamide chemotherapy.

The study of our series and the reports of other workers who have observed similar outbreaks impresses us with the fact that many factors remain to be studied before the entire field of acute respiratory infections can be charted and particularly is this true of those caused by a filtrable virus.

We agree with Francis that this can be achieved only by clinical epidemiological methods and that by comparing the clinical differences in patients and epidemics with specific laboratory data, the various entities will fall into their proper places in the puzzle of epidemic respiratory disease.

SYMPOSIUM ON WAR MEDICINE. II.

WAR AND MEDICINE*

HENRY E. SIGERIST, M.D.

I MUST begin by confessing that I am not an expert in this particular field of medical history. My researches have been along somewhat different lines, although I have touched the history of war surgery in several previous publications.[1] Men like Colonel Fielding H. Garrison[2] and Colonel Edgar E. Hume[3] have made infinitely more important contributions on which I will have to draw heavily. I am, however, extremely interested in the subject because, directly or indirectly, wars have played a very important part in the development of medicine, and also because during the last war I was an army physician myself. Since the subject is very broad, I must limit myself to tracing briefly the development.

War's contribution to medicine is, first of all, negative. It destroys the best results of the physician's work. The elite of a nation, young men trained and nourished scientifically, immunized against a great variety of diseases, are shot to pieces, are killed or crippled. War, however, affects also the health and well-being of the civilian population adversely because it is a catastrophe that usually does not come alone. War, famine, and pestilence have at all times constituted a triad of evils. The farmer has to abandon the plow, the fields are destroyed, the granaries are looted; famine and deficiency diseases result. Transportation is upset. After the Industrial Revolution the population increased in most western European countries beyond the productive capacity of the soil, so that countries had to rely on the importation of foodstuffs. The blockade, therefore, became one of the most formidable weapons, with the result that malnutrition and famines developed. Famine and pesti-

lence, more than the actual war, devastated Central Europe in the seventeenth century. It was a contributing factor in Napoleon's defeat of 1812. Scurvy played a very important part in the Sixth Crusade in the thirteenth century, but also in the armies of Napoleon in Egypt and Russia, and during the World War in the British army in Kut-el-Amara.

Every war was a fertile breeding ground for the development of epidemics. Large groups of people are massed, filth accumulates, the very subtle public health machinery is frequently upset, the physical resistance of the population is reduced by malnutrition or other factors, epidemics develop, and more than one war has been lost as a result. Greece was saved from Persian invasion in 492 by the outbreak of an epidemic that decimated the Persian armies. The plague of 429, the character of which is still controversial, accelerated the downfall of Athens. An epidemic stopped the Huns before Constantinople in A.D. 425. The Black Death of 1348 had tremendous repercussions on Europe's war history. England, equipped with the new firearms, had defeated the French at Crécy and had conquered Calais after a siege of eleven months. The plague forced them to withdraw and compelled them to sign a truce. The Scottish allies of France, who intended to invade the north of England, were not only defeated by the English troops but also decimated by the plague. The kingdom of Naples was saved by the plague which forced the Hungarian army of occupation to a hurried retreat.

From the Renaissance on, typhus was one of the most dangerous enemies, ever ready to defeat brilliant armies and to play havoc with the civilian population of many countries.[4] The louse was still triumphant in the eighteenth century, and in almost every European war of the period, including the campaigns of Napoleon, more people died from typhus than from wounds. Conditions changed in the second half of the nineteenth century when the battle between soap and the louse resulted in the latter's retreat for the first time. Typhus disappeared from most western European countries, and armies could destroy each other without interference. But the disease remained endemic in eastern Europe, and we all remember the part it played in the First World War, followed by the terrific devastations it caused in Russia from 1918 to 1922. We do not know yet what part typhus will play in the present war. It seems that the disease is still under control, and it is very probable that it will remain so for some time. The actual danger will come later when the war enters its decisive phase, when armies collapse, and civil unrest develops. Then typhus may again raise its head and play its traditional role in the shaping of history.

Until very recently disease caused more casualties than battle wounds. In the Crimean War the French army of 309,000 men lost 20,000 from wounds and 75,000 from disease, a proportion of almost 1 to 4. In the short Italian campaign of 1859, which lasted only two months, the French lost 8,674 men from disease and 3,664 from wounds. In our own Civil War typhoid and dysentery killed more people than the battles. The Franco-Prussian War of 1870 to 1871 was the first to reverse the proportion, at least in the German army. Germany lost 40,881 men, of whom 28,282 were killed by weapons, 346 died from accidents, and 12,253 from disease.

In the past, health standards of the civilian population were affected primarily by the food shortages and epidemics resulting from war. In the total wars of today a new factor has entered the scene. Today wars are fought not only by armies but by nations. Industrial production has become a major weapon and requires the mobilization of a country's entire man power including women. We have no figures yet, but we can readily imagine what health conditions must be among the millions of European workers who have been dragged away from their homes and are performing slave labor for Germany.

In our own country the sudden expansion of the war industries has led to a considerable dislocation of the population. Thousands of workers live in trailers and in shacks, or sleep in "hot beds" which are hardly conducive to health. Already the number of industrial accidents has increased, and we may also expect an increase in the incidence of tuberculosis, which is likely to happen when large numbers of women are drawn into industry. Under normal conditions industrial expansion would call for added medical facilities, but under war conditions the demand cannot be satisfied because the armed forces absorb a high percentage of the available medical personnel and equipment. Thus a vicious circle results which can only be offset by a thorough organization of all medical resources in a way that guarantees maximum efficiency and minimum waste.

There can be no doubt that the major immediate contribution of war to medicine is negative. War is a destructive process which destroys what medicine has endeavored to build. But war, on the other hand, is also a challenge and a stimulus to medicine, both technically and socially. Medicine is always facing a condition of emergency, because in the fight against disease there is no armistice. War, however, is an emergency of a particular kind which puts a nation's medical resources to a severe test. It also provides opportunities for experimentation on a tremendous scale, such as would never be available in times of peace.

Of all branches of medicine, surgery obviously is the one which at all times responded to the war challenge most strongly and in various ways. Armies travel and with them go the army surgeons. They meet colleagues from foreign lands and exchange experiences. This already happened in ancient Greece when Greek surgeons traveled with the mercenaries who were in the army of the Egyptian pharaoh Psammetich. They probably learned from their Egyptian colleagues, which may explain the fact that similar operations are described in the Egyptian and Greek surgical literature. Surgery is not only transmitted through books, but, first of all, in a practical way, with experience being passed on from father to son, from master to pupil. In this process of transmission wars must have played a very important part.

War was also responsible for the erection of hospitals in ancient Rome. The Greeks never had hospitals in our sense; physicians sometimes took a few patients into the guest rooms of their workshop, the *iatreion*, but these were certainly not regular hospitals. In Rome, however, practical considerations led to the establishment of special institutions for the care of certain groups of sick people. Every soldier was a fighting force, and it was in the interest of the army to restore the wounded as quickly and as thoroughly as possible. Lazarettos were, therefore, built, and the foundations of several of them have

been excavated, particularly in the periphery of the Empire. Some of them, like the one in Novaesium, were very elaborate institutions with many sick-rooms opening into large corridors built around a vast courtyard.[5] The military hospital in Baden, in Switzerland, was close to a sulfur spring, and extensive use was made of the medicinal water in the treatment of the wounded.

War, or rather the lack of war, caused the establishment of another kind of Roman hospital, the slave *valetudinaria*. Slaves were cheap as long as wars guaranteed a steady stream of prisoners. But the value of slaves increased considerably once the empire was pacified, and it became profitable to spend money for the restoration of the slaves' health. Thus slave hospitals were erected on the large estates of Roman landowners.

Until the fourteenth century most war wounds were caused by swords, spears, arrows, and similar weapons. They, as a rule, healed by first intention, and in the writings of thirteenth century surgeons wound healing without suppuration was considered the normal process that a physician should strive to attain whenever possible. Conditions changed when firearms were introduced in the fourteenth century. The wounds caused by the large caliber lead bullets of those days were primarily infected, and the view was generally accepted that gunshot wounds were poisoned by gunpowder and had to be treated with the cautery or by pouring boiling oil into the wound. It is well known how a military surgeon, Ambroise Paré, the father of modern surgery, refuted this view on the basis of experiences gained on the battle fields during one of the campaigns of Francis I against Charles V. He proved experimentally that gunshot wounds healed much better without the brutal treatment that destroyed so much of the tissues. But even to Paré suppuration appeared as the normal wound-healing process. Paré's treatise on the treatment of gunshot wounds was published in 1545 and revolutionized war surgery. Thereafter he published a large number of other surgical books, and frequent campaigns in which he participated gave him an opportunity to test his operations on a large scale. He reintroduced the ligature of arteries when performing amputations, was also a pioneer in the field of obstetrical operations, and exerted a tremendous influence in the whole field of surgery.

When John Hunter took part in the expedition to Belle Isle in 1761, the British navy availed itself of the services not only of a surgeon but also of a scientist. On this expedition Hunter gained invaluable experience on gunshot wounds, a subject that he studied all his life and which he finally discussed in his masterpiece, *A Treatise on the Blood, Inflammation and Gunshot Wounds,* that was published in 1794 soon after his death. In those days, most surgeons were still craftsmen who were primarily interested in the practical side of surgery. Hunter was a surgeon also, but a scientist in addition. For him a wound was something more than a practical problem. He was not content to ask, "How can I best heal this wound?" He inquired, "What does the wound signify to the organism? By what mechanisms does the organism safeguard itself against the effects of the wound, immediate and remote?" In this way, almost imperceptibly, he passed from the domain of surgery into that of pathology. The main significance of his work was that he threw open the field of surgical observation and experiment to general medicine. He was the first investigator

since the days of antiquity to advance the theory of inflammation, and there can be no doubt that Hunter's war experience had a great influence on his later researches.

Until the middle of the nineteenth century, the field of surgery was limited to a number of classical operations which had been gradually improved from century to century. Major abdominal surgery was impossible as long as one could not operate on the relaxed body, and also on account of pain and secondary infection. The introduction of general anesthesia in 1846, and of antisepsis in 1867, when Lister's first publications came out, liberated surgery from these age-old bonds. Both methods were immediately applied in war surgery and undoubtedly helped to save thousands of human lives. In 1846 Warren performed his historic operation at the Massachusetts General Hospital, while Morton gave the anesthesia, and the following year Syme applied general anesthesia in the Mexican War and Pirogov did the same in Russia. In 1867 Lister published his first papers, and a few years later the Franco-Prussian War provided an opportunity to apply and test the antiseptic treatment of wounds on a large scale and to gain much experience in the field. The German surgeons, Volkmann, Thiersch, and Mikulicz, were particularly active in developing and popularizing the method.

The Franco-Prussian War also became the testing ground for the efficacy of smallpox vaccination. In the German army, where most soldiers were vaccinated and revaccinated, 4,800 cases of smallpox occurred with 278 deaths, while among the unvaccinated French prisoners alone 14,000 cases occurred with 2,000 deaths.

All fields of medicine felt the challenge of war, surgery more than any other, but also public health was stimulated. Problems of sanitation were particularly acute in times of war, and in the seventeenth and eighteenth centuries many books were written on the sanitation of camps and barracks and on general problems of military hygiene. In 1738 a great soldier, the Maréchal de Saxe, wrote a book with the title, *Rêveries ou mémoires sur l'art de la guerre.* It was the result of thirteen nights of insomnia when he was suffering from a fever disease, not a textbook on strategy, but a thoughtful book on military hygiene. Uniforms were more spectacular than convenient. They were devised to satisfy the vanity of the ruler and to make the soldiers attractive to the fair sex as a compensation for the professional risks they ran. The Maréchal de Saxe advocated a different type of uniform better adapted to the purpose they had to serve. He also gave much thought to the soldiers' diet. Long before Liebig, in the middle of the eighteenth century, meat extracts were prepared to feed soldiers during campaigns.[6]

War had repercussions not only on medical science but also on the humanitarian side of medicine. Florence Nightingale would have become the reformer of nursing without a Crimean War, but there can be no doubt that the experience she gained at Scutari in those terrible years 1854 to 1856 accelerated developments tremendously. October 21, 1854, the day when she left England with 38 nurses, truly marks a turning point in the history of nursing. Placed all of a sudden under conditions of great emergency, Florence

Nightingale saw and did more in less than two years than she could have done in a lifetime in England. The Crimean War thus actually became the cradle of modern nursing, just as the Battle of Solferino in 1859 became the starting point of the Red Cross. The Geneva banker, Henri Dunant, who was visiting Italy as a tourist, suddenly found himself on the battlefield of Solferino and was so stirred by what he saw that he devoted his entire life to the alleviation of the sufferings of the wounded and prisoners of war. In October, 1863, 62 delegates, representing 16 nations, convened at Geneva, and the Red Cross Society was founded the following year. As we all know, it has extended its scope far beyond war activities and in every country is playing a tremendous part in relieving human suffering.

Ambroise Paré and John Hunter, whom we mentioned before, served as army surgeons, but only occasionally. Paré was surgeon-in-ordinary to several French kings, and it was obvious that he accompanied them whenever they went to war, but otherwise he practiced surgery as a civilian in Paris. John Hunter's military period was only an episode in his life, although an important one. Great contributions have been made to medical science, however, by medical men for whom the army was a career, and there can be no doubt that no medical corps in the world has done more for the advancement of science than that of the United States Army. It is impossible to list all these contributions, and all I can do is to recall a few names: Beaumont who experimented in the wilderness on the gastric juice; John Billings whose contribution to hospital construction, medical education, vital statistics, and the development of libraries has been unsurpassed; the heroic work on yellow fever of Sternberg, Reed, Carroll, Lazear, Agramonte; Gorgas whose activities extended far beyond the Panama Canal and who was instrumental in organizing medical services in the gold mines of South Africa; Ashford's studies on hookworm, Craig's on malaria, Woodward's on photomicrography. Colonel Hume has recently shown in a scholarly publication what great contributions army surgeons made to the science of ornithology.[7] There is hardly a field of general or medical science that has not been enriched by members of the United States Army Medical Corps, and the Army Medical Library in Washington with its splendid collections and bibliographies is a unique institution that has played an important part in the development of American medicine.

There is one thing we can learn from history, namely, how tremendously important the medical corps is. There was a time, not so long ago, when the generals used to consider the medical officer a nuisance, the man who always interfered with their dispositions. They forgot how many campaigns were lost in spite of brilliant strategy as a result of diseases. Views are changing rapidly, and the war departments are recognizing the need for mobilizing all the resources of medical science.

Medicine learned from every war, and the more science progressed the more medicine became able to save human lives even in war. The soldiers who today are sent to foreign lands are immunized against many once fatal diseases; they are nourished scientifically and they carry along the vitamins needed to protect them from deficiency diseases. They are clothed infinitely

more hygienically than in the past. Operative results have been greatly improved, and the new methods of blood transfusion are saving countless lives. The great progress achieved by orthopedics makes it possible to rehabilitate the wounded infinitely better than in the past. In previous centuries little attention was paid to crippled war veterans. A few were assigned to the care of monasteries, but the great majority became beggars roaming the streets. It was Louis XIV in France who established the *Hôtel des Invalides* in Paris, an institution in which invalid veterans were attended at the expense of the state.

The rehabilitation of the crippled veterans is one of the most important social problems of war medicine today. Pensions alone do not solve the problem. Work is one of the major balancing factors of health, and there is plenty of skilled labor that can be performed by blind and maimed veterans. Every effort must be made to readjust the invalid to his environment so that he can continue to live as a useful member of society and thus preserve his self-respect. The Soviet Union is handling the problem in an admirable way. Special schools have been established for the purpose, giving general and vocational training in courses that may last as long as two years. Invalids who had only elementary education may improve their general knowledge by taking courses of secondary education. Vocational training produces bookkeepers, technicians, agricultural experts, tailors, photographers, telegraph operators, etc. The Commissariats of Social Welfare are in charge of rehabilitation programs. Local social welfare bodies must place invalids within two days, and all industrial and other enterprises are urged to provide suitable work and housing for the veterans, who are visited by special commissions every month.

War is not a natural catastrophe or a biological process, as has sometimes been said. It is man made and represents a primitive method of conducting international politics. Civilization is a very young phenomenon in the history of mankind, so that we should not be astonished that relapses into primitive savagery still occur. There is no reason, however, why we should not be able to develop in the course of time from a competitive to a cooperative society on a world-wide scale. As long as wars occurred they always had definite results that affected social and economic conditions of the countries involved in a way that was either detrimental or beneficial to the development of medicine.[8]

The campaigns of Alexander the Great propagated Greek culture all over the ancient world and created conditions favorable to the development of medicine in such countries as Egypt and Syria. The Roman conquest of western Europe pacified the Germanic tribes, developed trade, and permitted cultural developments that also benefited medicine. Persian medicine flourished as never before after the Arabic conquest, and Persia became an important province of Islamic civilization.

The Thirty Years' War, on the other hand, was a strongly retarding factor, not only on account of the destruction it brought all over central Europe, but also because it perpetuated feudalistic trends. The emergency created by the revolutionary wars of France greatly accelerated the reorganization of medicine initiated by the revolutionary government. The reforms were continued by Napoleon and became the foundation upon which the French school developed and flourished. The Franco-Prussian War liberated France from

the rottenness of the Second Empire, and led to the establishment of the Third Republic under which science and medicine reached great heights. The World War of 1914-1918 stimulated medical science in many ways as we all remember. Yet the contribution of that war to medicine was probably still greater in the field of social medicine. The war had demonstrated the importance of protecting the workers' health, and industrial medicine developed as never before. Workmen's compensation was introduced in a number of countries, and general health insurance in France. Various countries established ministries of health, and the Soviet Union made a totally new departure in creating the type of medical organization best adapted to the new industrial society and the new technology of medicine.

In the United States the examination of almost three million drafted men revealed that 47 per cent were defective; in other words, that health conditions were not as good as they could have been and that there was a maladjustment in the distribution of medical care. The Committee on the Costs of Medical Care was founded. Other agencies joined in the work, and for ten years surveys were made that provided us with the facts and figures needed for intelligent planning.

The war in which we are engaged at present will undoubtedly again stimulate medical science, but I am convinced that its social effects will be much more strongly felt. It would be foolish to assume, as some people do, that Europe is finished. Europe is going through one of its periodic crises, and the very destruction will force the European nations to reorganize their social and economic structure from the bottom. Thus conditions may well be created that will enable medicine to develop more rapidly and more broadly than in the past.

The war is demonstrating to us that our technology has outrun our sociology. We have created ingenious machines, but not the social and economic organization that an industrial society requires. We have built means of transportation that overbridge the continents, but not the apparatus that insures peaceful cooperation between nations. The same happened in medicine, and now, under pressure of the emergency, we have to organize medical services, not only for the armed forces but for the nation. If we learn a lesson from this experience, it may well become this war's greatest contribution to medicine.

BACTERIAL WARFARE

The Use of Biologic Agents in Warfare

Colonel Leon A. Fox, M.C., U. S. Army

Editor's Note.—This article was first published by Colonel Fox, then Major Fox, in March, 1933. It has been republished and quoted extensively in technical military periodicals. It was republished in The Military Surgeon in May, 1942. The author states that, while some advances have been made since the original publication of this article, the principles are as applicable today as when first stated.

BACTERIAL warfare is one of the recent scare-heads that we are being served by the pseudoscientists who contribute to the flaming pages of the Sunday annexes syndicated over the Nation's press. This question of bacterial warfare has been brought forward from time to time since the World War. The use of the organisms that cause communicable diseases as an instrnment of warfare was considered by the Conference on the Limitation of Armaments held in Washington in 1922. An international commission consisting of Professors Pfeiffer (Breslau), Bordet (Pasteur Institute), Madsen (Copenhagen), and Cannon (Harvard), appointed at the time, reported to the League of Nations essentially as follows: (a) The effects of bacterial injury cannot be limited or localized. (b) Modern water purification methods protect against the organisms of typhoid and cholera. (c) Plague is a disease that would be as dangerous for the force using the organisms as for the attacked. (d) The danger from typhus has been exaggerated. (e) Modern sanitary methods are effective in controlling communicable diseases.

Following this pronouncement by these eminent scientists, the question of bacterial warfare suffered a lapse of interest; but during the past year, as an incident of the preparation for the Geneva Convention, there has been a marked revival of interest in this supposed bugbear, bacterial warfare. Possibly this is only a part of the effort of professional pacifists to add all the imaginary frightfulness they can picture to the known real horrors of war.

The space and thought that have been given to this question by feature writers have not been without effect, and many people now believe that bacterial warfare represents a real threat and problem for future generations. Many are now associating chemical warfare and bacterial warfare, with the result that in the resolution of adjournment, voted by the General Commission of the Disarmament Conference on July 23, 1932, at Geneva, we find chemical, bacteriological, and incendiary warfare grouped for consideration. The mere fact that this great body of peace workers considers bacterial warfare seriously enough to prohibit its use justifies military men in considering this agency of

Reprinted from The Military Surgeon 90: 563, (May), 1942.

warfare. We know how little treaties protect; so we should study the question to see if the use of biologic weapons is a real problem for the military minds of the future.

Under biologics we include all those organisms that may invade the body of man or animal to produce disease, so that while we use the term bacterial warfare, we do not limit this paper to a consideration of bacterial diseases. We will also consider the filtrable viruses, Protozoa, and other pathogenic forms as well as their toxic products.

With the powers of the world in session at Geneva discussing the future of warfare, and with some of the great nations of the world recommending the complete abolition of chemical warfare, it may appear strange to have one consider biologic warfare. I believe all will agree that while it is a mistake to live in the past, it is equally undesirable to ignore the lessons of the past in prognosticating regarding the future. It is therefore well, before we consider the possible use of biologics in warfare, to discuss briefly the question, Will the nations of the world abandon the use of chemicals as an instrument of warfare?

Every advance in thought or design meets reaction and antagonism from the minds of the previous generation. It does not take some radical departure from the accepted views of the day, such as marked the revolutionary concept of Copernicus or Darwin, to start all "as is" conservatives on a tirade of opposition with the usual tenor of their remarks: "It is against the law of nature," "It is against religion," "It conflicts with all known law," "Even if true, it does not fit into the existing order of things." A man of middle age today may remember the old mossback who refused to ride on the train of the nineteenth century. In fact, the train and street car had not completely overcome all the pooh-poohs of the backward ignoramus until they were involved in a fight for their very existence with a newer means of transportation—the motor. The motor vehicle had just had time to have a proper road net constructed when this engine, becoming "air-minded," needs no roads. Have they been generally accepted? Certainly. However, remarks such as, "If God wished man to fly he would have given him wings," were made in the pulpits of this country during the present century.

It takes more than the harpings of the minds of yesterday to scotch the wheels of progress. It may startle many to talk of world progress in connection with implements of warfare. However, it is not believed that any fair-minded individual can deny the place in world advancement that is due to the spirit of conquest. The peaceful shepherd, content to watch his flocks, has added little to the world's knowledge. The trader and warrior have discovered and spread knowledge. Trader and warrior are almost inseparably associated throughout history, and slowly as they may have progressed, they usually lead the thought of the day. The spirit of adventure and discovery has always marched with the warrior. The discoveries of the warrior are not limited to implements of war; however, these are the factors we wish to consider. In this field again we meet the same antagonism at every advance that the fighting man has made, an antagonism that has affected all minds of the "as is" type, including conservative and reactionary individuals. Every advance, every discov-

ery of a new weapon by the fighting man, has had to overcome two groups of opponents: (1) The fixed and established military group that is always sure the new weapon "won't work," "Is not as good as older weapons," "Not practical," etc., (2) The pacifist group—the shepherd group, that considers each new weapon more terrible than the former and cries out against it.

Primitive man in his combats certainly had no weapons. Are there any today who believe that this early creature did not fight over "food and females?" It may be added that all combat ultimately resolves itself in the final analysis to a strife for one of these basic biologic requirements—nourishment or sex. Fighting over gods was a later development; and these fights over gods were over a personal God, a God of the land or tribe, a God to favor their own special country, a benevolent God who would make their country a more bountiful place to live.

In the early combats man could only bite and claw and choke an adversary. This was the day of brute strength. Cleverness had relatively little value. The first man to use a weapon was the man with the best mind of his day. The first weapon used must have been very simple and elementary. Possibly a hard object held in the hand with which he brained his opponent. This weapon possibly did not create much comment. This was not an age of comment; however, the descendants of the type that could not learn to use this weapon are not numerous. Has this weapon been abandoned? Certainly not. It is an excellent weapon, and no good weapon has ever been discarded. Its use today is very limited because of the discovery of other weapons of greater range and effectiveness.

Development of weapons has always been for the purpose of using intelligence to overcome mere physical force. The factor of range, killing an opponent before he can close with you, is a most important factor when the man of intelligence must meet superior physical force or number. Probably the first weapon to provide range was a club, possibly a sharp stick, the forerunner of the iron-tipped spear. The club may have had a stone head attached. These weapons not only advanced the clever man over the mere strong man; they aided man in his fight with the man-eating animals of the time. However, if we can make deductions from the early cave records of men of this period, advance was slow because the intelligence was of such low order that they were slow to understand and accept these new weapons. The race improved because the thinker, the successful warrior, lived and won the females and left descendants; the slow and reactionary type did not live to reproduce. With every advance in weapons man is giving evidence of a desire to overcome brute strength by means of a weapon with range and effectiveness.

We can picture the introduction of the early propelled instruments, such as the arrow, causing a storm of opposition. Some youngster designed some form of propelling instrument for a sharp stick and possibly suffered the jeers of the snaggled tooth elders as he shot the sticks into inanimate targets, and received only the reward of complete recognition when he shot a sharp stick through the belly of an old pack leader to take over a band of cowed females. The progeny of this genius were of a higher order of mentality and possibly soon learned the

value of organization, with the result that a tribe of arrow users developed. This seemed like the final advance, and who can doubt their ability to inflict their will on the men of the time.

The fact that the conquered men, possibly of superior physical development, considered the weapon a cruel and brutal implement that God had not endowed man with did not cause it to fall into disuse. The only thing that caused this weapon to fall into disuse, and finally be practically abandoned, was the development of such protection as caused the implement to cease to be effective or because other instruments were designed of greater range and effectiveness. These factors are the only things that have ever caused a weapon used successfully to be abandoned.

The outcry against the use of chemicals seems to people of this day to be quite a serious factor, and some wonder if their use will be curtailed by this influence. The following factors should be considered before we make a decision: (a) No effective weapon once introduced has ever been abandoned until it was displaced by a more effective weapon or protection was developed that rendered the instrument useless. (b) The hue and cry that attended the introduction of chemicals are not unusual on the introduction of a new weapon. The early use of gunpowder produced a reaction in every respect similar to the cry of the present day pacifist against gas. Will the use of chemicals in warfare be abandoned? Probably not. Will the use of chemicals be curtailed? Certainly; just as certain as the race progresses, just as certain as new and more effective weapons are designed—not before this advance is made.

Will the next advance in warfare see the use of biologics? Will the next agent used be the living organisms, bacterial warfare, the scourge of armies from the most ancient times—the communicable diseases? The question of biologic warfare will be considered in more detail because here again we run into the most elaborate and fanciful statements.

A review of military history will reveal the great influence that disease has played in past wars. Results have been decisively influenced in many campaigns by epidemics of communicable disease. In some campaigns they have caused such tremendous losses and such great numbers of noneffectives that the combat has reached a stalemate. However, in certain instances, for unknown reasons, there has been a great difference in the degree to which combatants have reacted to the epidemic conditions. In a few cases we are able to understand why the communicable diseases appeared to have greater invasive power toward one of the armies; in other instances we do not understand clearly why there was a difference in the degree of involvement of the forces.

Volumes have been written on the epidemic diseases that have attacked the military forces. We will not attempt to review this extensive literature, but the doctor, especially the epidemiologist, knows that the student of history who reads only of tactics and strategy, the victories and defeats of a campaign, without familiarity with the medical history of the war, is likely to give some commander credit for success or failure that all too often has been caused by some epidemic of communicable disease. This is not meant to depreciate military success, for

the great general is often a great sanitarian, and even Alexander may owe a part of his success to his doctor, philosopher, teacher—Aristotle's advice to "boil his water and bury his dung."

We must remember that we can march through the pages of military history all the way to the twentieth century before we come to a campaign where the missiles of the enemy produce more casualties than epidemic disease. In most of the ancient campaigns of any duration some one of the great military plagues did more to decimate the military forces than all the man-made munitions. I say one advisedly, although often many infections raged and famine and scurvy accompanied the communicable diseases.

What was the nature of these ancient pests? Were they diseases of that age now no longer known? No, the military pests that existed then are still with us. The Big Six of all time (wartimes) are: (1) the enteric fevers, typhoid and the paratyphoids; (2) the dysenteries; (3) cholera; (4) typhus; (5) the plague, bubonic plague, the Black Death; (6) smallpox.

Do not consider for a moment that the above diseases had any monopoly on the right to destroy armies. It is probable that at times influenza and the epidemic pneumonias took such heavy toll that only little fuel was left to be consumed by the Big Six. Again, under conditions where malaria is endemic, this disease is second to none in the production of noneffectives in military ranks. In fact, measles and epidemic meningitis may well be added to the list of military scourges.

This paper is not for the purpose of considering the epidemic conditions of the armies of the past, but it is realized that many individuals will naturally consider that if these infectious agents were able to produce such frightful outbreaks of disease by the simple process of chance infection under natural conditions, then in the hands of man, as a military weapon, they may well prove even more destructive. They may fail to consider the fact that the same measures that are now so efficacious against the chance infections occurring in nature may prove of equal value in combating the same agency of destruction when used by man.

We have presented biologic warfare in all its horrors; now let us analyze the problem in detail. What agents can be used to produce death and disease? How can these agents be introduced into the bodies of the enemy? We will discuss these questions in the order stated. The biologic agents available for warfare are: (1) the communicable diseases; (2) other infective processes (such as wound infections); (3) toxic products of bacteria.

The communicable diseases are well known. They are the so-called transmissible diseases that produce epidemics. They are caused by a living contagion and are spread from man to man or animal to man by various channels of transmission. All of the Big Six and the other diseases mentioned above belong to this group.

The second group, the other infective processes that are available, include such infective materials as the agents that infect wounds: gas gangrene, *tetanus*, anthrax, and other wound contaminations that are infectious but not communicable.

The last group of dangerous agents are the *toxic* products of bacterial growth. We will mention but a single terror-inspiring example—botulinus toxin.

A portion of this toxin almost inconceivably small when introduced into the body by any channel is lethal. We will give details later.

No one will question the effectiveness of all these agents in producing casualties when introduced into the bodies of unprotected and nonimmunized individuals. The important question then is how? How are these agents to be introduced into the bodies of the enemy to produce casualties?

Any consideration of the deliberate use of pathogenic organisms as a means of warfare will have to consider the question of how to produce a destructive epidemic in the forces of an opponent and at the same time protect one's own forces from invasion by the virulent organisms in question. Certainly at the present time we know of no disease-producing microorganisms that will respect uniform or insignia, and the use of bacteria in warfare for the destruction of opposing forces will have to be predicated upon the successful prior immunization or the complete isolation of the forces employing the disease-producing organisms through some system of quarantine.

Any intelligent discussion of bacterial warfare must certainly give detailed consideration to the question of how the living contagion is to be introduced into the individuals that are to be infected. We can well begin this investigation by a study of the channels of infection. The communicable diseases may be classified on the basis of their "routes of transmission." By this is meant the path that the living contagion follows when it leaves the body of the sick man or animal, or in some cases the carrier, to enter the body of the susceptible host to produce disease. On this basis we may classify the communicable diseases into intestinal diseases, respiratory diseases, direct contact diseases, and insect-transmitted diseases.

The intestinal diseases are produced when some small portion, usually a microscopic portion, of the material from the intestinal canal of the sick man with its living microorganisms, is introduced into the alimentary canal of the susceptible individual. Typhoid, cholera, and dysentery are well-known examples of this type of disease.

The respiratory diseases, sometimes known as "sputa-borne" or even "air-borne" diseases, are the communicable diseases spread by the transmission of living microorganisms from the respiratory tract of the sick to the respiratory tract of the invaded. This group of diseases is of tremendous importance and embraces such conditions as the common cold, influenza, pneumonia, diphtheria, epidemic meningitis, smallpox, and possibly of special importance for war purposes, the pneumonic form of bubonic plague.

The group of diseases that we refer to as "insect-transmitted" are those where the invasion of the new host is effected by the bites of insects which have previously fed on an individual—man or animal—infected with the disease in question. A period of incubation on the part of the insect between feedings on sick and feedings on individuals to be infected is necessary in certain instances; with other diseases such interval is not required. Examples of insect-transmitted diseases that require an interval for the development of the contagion within the body of the insect after feeding on the infected individual are malaria and yellow

fever, both transmitted by mosquitoes. Bubonic plague, a disease of rats that is transmitted to man by the bite of the rat flea, does not require an incubationary period for the rat flea to develop infectiveness.

The venereal diseases are direct contact diseases. They are of profound military importance and have proved decisive factors in certain past wars, notably influencing the European campaigns of the fifteenth and sixteenth centuries. The deliberate use, however, of this means of injury is fraught with difficulties when we plan a method of securing personnel to effect the necessary exposure. The soldier's danger from the venereal diseases will not come from the open, avowed wartime enemy who loves him least, but from the money-loving or uniform-worshipping ladies who profess to love him most. Therefore, while these diseases may at times exceed all other causes of military noneffectiveness, we can dismiss them without further discussion while we are considering bacterial warfare.

It follows, then, that the communicable diseases that constitute an epidemic or pandemic threat to the military forces are the intestinal, respiratory, and insect-transmitted diseases.

THE INTESTINAL DISEASES

Mankind is all too familiar with the terrible epidemics of typhoid, cholera, dysentery, and the diarrheal conditions that have destroyed military forces in the past. However, it is highly questionable if this group of diseases will ever in the future cause any such terrible catastrophes, for the reason that the epidemiology of these infections is so thoroughly understood that modern sanitary methods and immunization processes have rendered comparatively innocuous these hazards of earlier armies.

The deliberate use in warfare of these agents, however, we shall consider. While occasional small outbreaks of these diseases may be due to food infections, real epidemics of this group of diseases are traceable only to infected water and milk supplies, or to such a complete sanitary breakdown that general fecal contamination of food supplies occurs. The possibility of contaminating a milk supply presents practically insurmountable difficulties, although it is theoretically possible that spies might use such a means to discommode and harass civil populations. Of course, it has no practical application to the military forces themselves.

Contamination of water supplies of civilian communities by means of infection of large reservoirs and storage basins where the water is held awaiting consumption is a possibility. Contamination, to be effective, would have to be subsequent to treatment by the modern water purification plant consisting of filtration and chlorination, or, of course, it would be valueless; but this is within the range of possibilities, and it is possible that future wars will reveal that spies will make an effort to contaminate municipal water supplies.

The use of the intestinal group of diseases against forces in the field would probable prove entirely ineffective because modern water purification methods and the close supervision of the water supply that is accepted as a necessary incident of military service will absolutely preclude the successful employment of this means of combat.

In considering the intestinal group it may be well to stress the fact that the reason modern armies, and for that matter all civilized communities, do not have serious epidemics of these diseases is not that the infective agents that cause these diseases are not present or available, but that modern sanitation protects the personnel.

Let us take a typical example, typhoid fever. The incidence of typhoid in our civil population has been greatly reduced during the present century. Let no one think, however, that this is due to any scarcity of the typhoid bacillus, and it must also be remembered that the civil population has not had any general immunization such as helps to protect the Army. Typhoid has not retreated to the outskirts of civilization: it is all about us. Every state, yes, every county in the Union, is infected. Typhoid carriers in the United States possibly number 100,000 and are generally without supervision. The reason we have only about 5,000 deaths from typhoid fever per year in the United States of America instead of about 100,000 deaths is that the great mass of our people now use water that has been rendered safe by filtration and chlorination. They consume milk that has been pasteurized and other foods that have been protected.

The same statement may be made concerning the low incidence of the dysenteries in our country. The infection is present, but epidemics do not occur because our sanitary measures are effective. We need not fear infection from without with this group of diseases; we are already grossly contaminated.

The die-hards will say that cholera is not so easily handled and is not at present a problem in America. Granted. We do not have cholera in the States; but our Army and our people do live in the presence of cholera without having epidemics of the disease. The Philippine Islands, where our Army maintains an effective fighting force entirely free from this terrible scourge, has a carrier incidence of the vibrio that causes cholera that is always high. The intestinal group of diseases will certainly not prove destructive against any civilized nation that cares to pay the price of the protection that modern sanitary methods provide.

THE RESPIRATORY DISEASES

In leaving the intestinal group of diseases we proceed from the problem that represents the greatest triumph in preventive medicine to the group of diseases that baffles the best efforts of all health workers. In the control of the intestinal diseases we have so much to be proud of. In preventing the respiratory diseases we have accomplished so little. This is stated with a full knowledge of the wonderful results that have been obtained with smallpox vaccination, and the immunization to diphtheria by the use of toxin products, as well as with a full realization of the fact that we are on the threshold of equally great accomplishments in controlling scarlet fever.

It should be noted that these great accomplishments are not sanitary triumphs, such as glorify our work with the intestinal group of diseases, but immunization processes. Not being able to prevent the infection reaching mankind, we take advantage of the fact that familiarity with the organism, while not breeding contempt, does produce immunity. Therefore, we use the only method that appears to offer any great protection against the respiratory dis-

eases in nature, namely, immunization. It must be admitted that health workers can accomplish practically nothing in the way of protecting peoples from infection with the great host of respiratory invaders, and such protection as we have is due to either natural or artificial exposure to these organisms.

In this group of diseases we find a number of maladies that are serious enough to be effective war weapons if ways of using them can be devised. However, before proceeding we should call attention to the fact that in this group are also a large number of diseases that are not suited for military purposes. For instance, smallpox, while a very serious epidemic disease, must be dismissed immediately. All military forces are immunized to this dreadful scourge, and we can, therefore, dismiss it from further consideration.

Many of the diseases of childhood, while constituting a military problem at time of mobilizing rural recruits, are not suitable for military purposes for the reason that the factor of age susceptibility plays so much importance when we consider the entire group that comprises our population. As an example we may mention diphtheria. While in childhood a very high percentage of the population is susceptible to this disease, the great majority of these same individuals develop considerable natural immunity to the organism that causes diphtheria without further interference than the normal aging. Therefore, while we see epidemics of diphtheria in schools and orphanages, we do not encounter serious outbreaks involving large numbers of any adult population. This disease is cited only as an example wherein the factor of age susceptibility is important; there are a number of diseases that show this phenomenon and would, therefore, be unsuited as offensive military weapons.

Certain conditions such as influenza, pneumonia, and the common cold do not show a marked tendency to limit their injury to any one age group and would be efficacious if they could be used against military personnel. Mankind is as helpless today as at any period in history in the control of these diseases; also they are very serious conditions that produce great numbers of noneffectives, and in the instance of the epidemic pneumonia they result in a tremendous mortality.

Before we surrender to the individuals who threaten such frightful havoc with this group, we may well ask how are they going to start an epidemic of influenza, pneumonia, or the common cold. If they answer that they will introduce the germs that cause these diseases, we can well laugh at them. The process is not so simple. The factors that make respiratory epidemics are not so elementary. They include not only the infection of the individual, but the question of the resistance of the infected animal. The organisms that cause these diseases are all about us. They are always with us. Epidemics mean more than simply infection; they mean the rapid transfer from individual to individual of these infective agents. They mean a lapse in the immunity of the invaded, and possibly something else.

I do not know of a bacteriologist or an epidemiologist who can tell you how to start a respiratory epidemic unless the stage is especially set. I know many who are certain that whenever you place a large group of individuals, man or beast, under poor hygienic conditions, with overcrowding, poor ventilation,

and exposure to unfavorable climatic conditions, or other factors that decrease resistance, respiratory outbreaks will occur in spite of any precautions that can be taken, and that if large numbers of highly susceptible individuals (rural populations) are present, the outbreak can be expected to assume epidemic proportions.

It is also worthy of note that when epidemic conditions prevail, certain organisms may possibly have greater invasive power, for then apparently populations that were not so susceptible or readily invaded may be attacked when they previously escaped injury. It will be noted that as in the case of the intestinal diseases, so with the respiratory diseases it is not a simple case of introducing infection that constitutes a menace. The organisms that produce most of these diseases are always with us, and epidemics mean more than infection. While we cannot understand exactly how epidemics start, and we question the ability of a military agency deliberately to produce an epidemic of one of these diseases, we feel certain that if bacterial warfare is ever contemplated, they will not think of using the respiratory group of invaders for the reason that quarantine, isolation, and all other methods to control diseases such as influenza, are practically valueless. The torch once set off might destroy friend and foe alike, and would, therefore, prove of no value as a military weapon.

The two diseases in this group that are most frequently mentioned are influenza and epidemic meningitis (cerebrospinal fever), possibly because of their importance during the World War. All that has been stated above applies with especial force to influenza, where in addition to the fact that no one knows how to control this disease, we must add that we are not even positive about the actual organism that causes the condition. Epidemic meningitis, on the other hand, is a very definite, specific disease due to a very well-known organism. We must admit at the outset that this is a very serious disease, and that it often assumes epidemic proportions in military organizations. However, if we stop to consider the nature of the organism and the epidemiology, we see how entirely unsuited epidemic meningitis is for use as a military weapon. The organism, the micrococcus of Weichselbaum, is so delicate that even on the most favorable culture media it rapidly dies when exposed for even a few hours to temperatures much below that of blood heat. This disease is spread by carriers, and the organism must be introduced almost directly from the nasal pharynx of the carrier to the respiratory mucous membrane of the individual invaded or it will be destroyed by the unfavorable temperature conditions while en route.

Those individuals who think this disease may be used for military purposes will answer that carriers in the forms of prisoners, etc., would be introduced into the opposing forces. To those who know anything about epidemic meningitis this suggestion is ridiculous. Any military aggregation of any great size already has so many carriers present (anywhere from 2 to 30 per cent) that the introduction of a few more or less is of no moment. Epidemics of meningitis occur only when *overcrowding* is associated with conditions that lower the general resistance, as exposure, unfavorable climatic conditions, and fatigue. Meningitis is, and probably always will be, a military problem; but the individual's friends and associates, not the enemy, are the great problem with this disease.

We will not take up in detail all of the various respiratory diseases. The tabulation would prove tiresome, for the story would always be not so much a question of the great danger of the introduction of the infective agent, but the creation of epidemic conditions, a soil in which the organism could produce an epidemic, overcrowding, and lessened resistance.

THE INSECT-TRANSMITTED DISEASES

These diseases will probably most certainly influence wars of the future as they have in the past. An invasion of such a country as Mexico, at the present time, could constitute more of a sanitary than a military problem. With malaria, dengue, and possibly even yellow fever along the seaboards, and typhus endemic in the plateau district, our main problems would be sanitary. Bubonic plague might also be encountered here as well as in any other place. This disease, bubonic plague, is the disease entity that many consider best suited for military purposes. To begin with, it is a frightfully serious malady, a decimating disease that has most profoundly influenced warfare in the past. It is possible that the rise of the Mohammedan world was due to a great extent to the fact that Europe was in the throes of the greatest scourge mankind has known, the plague, at the time that Mohammed's followers were ready to organize and extend the influence of the crescent until the horns were about to encircle the Mediterranean. Certainly these Arabian tribesmen had never shown any signs of military greatness or valor prior to this period, and it is probable that their religious ardor would have met with small success against the well-organized nations of the time if these nations had not been practically exsanguinated by the "Black Death."

The use of bubonic plague today against a field force, when the forces are actually in contact, is unthinkable for the simple reason that the epidemic could not be controlled. Infected personnel captured would provide the spark to set off possible outbreaks of pneumonic plague in the ranks of the captors. Infected rats would also visit and spread the condition. An advance over terrain infected with plague-bearing rats would be dangerous. Therefore, except as a last desperate, despairing hope of a rapidly retreating army, the use of plague by forces in the field is not to be considered.

The use of plague to harass civil populations presents less difficulty than the use of the organisms against a field force. Those who think that plague will be used as an offensive weapon consider that civil communities may be infected by introducing plague-infected rats. Of course, this is easier to state than to accomplish, but it may be possible for airplanes flying low to drop recently infected rats. At least this is the statement that the individuals make who consider the use of this weapon feasible. Even with so terrible a pandemic disease as plague, however, there is a great deal more to the question of epidemics than mere infection. For instance, to cite an example, one that Gill so forcibly states, "Not half a dozen cases of plague occurred amongst Europeans (including British troops) stationed in the Punjab during the year 1924, when about 500,000, or one-fortieth of the indigenous population suffered from the disease."[1] If these intelligent people were able to avoid the infection when residing in an environment that was literally infiltrated with the infection, it certainly should be possible to control bubonic plague in a population such as we have.

For that matter, the question of plague is not a condition that takes us to the outskirts of civilization. Our own Pacific Seaboard became infected in 1900, and following the San Francisco earthquake the infection extended and is now more or less endemic as a rodent disease, involving not only rats but also ground squirrels. Here again it is not a question of can we control the infection; we are controlling it, and we have not had an outbreak of human plague of sufficient size to designate as an epidemic.

The other insect-transmitted disease that is most frequently assigned a place of importance as an agent suited for warfare is typhus. This disease is certainly terrible enough to satisfy even those individuals who are anxious to preach the gospel of frightfulness. The military and civil populations that have been destroyed by typhus bear witness to how effective this agent of destruction can be. However, again we have a condition that is easily controlled. Complete solution of the problem of endemic typhus is not yet in print, although it is probable that the work of such men as Dyer, Maxcy, and Zinsser will soon offer a complete explanation of how this scourge simmers along during the interepidemic periods. Epidemic typhus is thoroughly understood. The epidemiology is so simple that it can be embraced in the name of the transmitting insect, the body louse. The control of epidemic typhus is the simple question of the control of louse infestations. Of course, quarantine will help to prevent the introduction of the infection, but quarantine is futile if the Army is allowed to become lousy. The lousy Army may become the victim of typhus, even in America, without the introduction of infection from extraneous sources. The weight of opinion in the minds of best epidemiologists is that, as Maxcy suggested, endemic typhus is probably carried over between epidemics in a rodent reservoir. Endemic cases occasionally occur when transmitted to man by an insect, and when the infection is passed from man to man by the body louse, with the resulting enhancement of virulence, epidemics may be expected to result.

The difficulty of starting an epidemic of malaria, yellow fever, or trypanosomiasis (sleeping sickness) appears to be obvious, for no one has suggested the use of these agents. Those who understand the epidemiology of these diseases know they are not suited for war purposes even though they realize the problem they present to military forces in endemic areas.

This completes consideration of the communicable diseases. We have discussed in some detail practically all except the direct contact group. The only diseases of this group of great military importance are venereal, and we have given our reasons for dismissing this group from consideration.

THE INFECTIVE PROCESSES

Certain disease processes that affect the tissues are caused by living organisms and are, therefore, designated as infective, even though they are not considered communicable in the sense that they tend to be transmitted from man to man. These disease processes include such infections as tetanus, gas gangrene, anthrax, and the ordinary pyogenic (pus formers) invaders. The agents that produce these infections have all been mentioned as possible war weapons, and it must be admitted that so far as the first three are concerned, with some scientific judgment on the part of their sponsors.

The agents that cause tetanus, gas gangrene, and anthrax are not delicate organisms such as the relatively short-lived, easily destroyed pathogens that cause most of the communicable diseases. They are very resistant, spore-forming organisms, generally capable of a prolonged period of viability without loss of virulence, even when separated from the animal tissues. It is not surprising, therefore, to find one of this group (anthrax) selected as the infectious agent best suited for military purposes by a science student preparing an undergraduate thesis on "Bacteriologic Warfare."[2] The selection of anthrax does credit to his training. In fact, the entire study shows more intelligent thought than any article that has come to the attention of the writer. His description of the characteristics of the proposed bacterial invader are worth quoting:

> What shall we say are the requirements for a perfect military pathogen? It attacks preferably both man and animals. It must be quick-acting, highly virulent, and capable of causing disease in small quantities. It must be highly resistant, capable of surviving outside the body under the most adverse conditions, and even resisting partial cooking or a careless attempt at sterilization (a spore former). The causative organism should be able to force its entrance through all the avenues of infection; respiratory tract, alimentary tract, and breaks in the skin. The disease should not be too actively contagious, and it must be very well understood, for pathogens should never be used without contemplating the possibility of their getting out of control. Finally, and perhaps most importantly, it should be possible to obtain large quantities of the pathogen in virulent strain and spore form with the least possible manipulation and delay.

After this excellent description of the perfect hypothetical agent, he selects anthrax as the agent best suited to meet the requirements of a bacterial weapon. I cannot agree with Pentler that "Anthrax satisfies the requirements almost perfectly," but I believe all bacteriologists will agree that he has selected the agent that most nearly meets the requirements he has so well outlined.

These spore-forming invaders are a real problem. Tetanus and gas gangrene are pathogenic processes that have always been associated with gunshot wounds and are, therefore, of special interest to the military surgeon. They do not produce epidemic diseases, however, and they are not communicable. They have to have a portal of entry made for them, a wound, and while the use of these organisms to contaminate battlefields might cause an increase in the number of cases of tetanus and gas gangrene, they would not increase the number of casualties. They would only complicate the treatment of those already disabled. It might be added that we have an entirely satisfactory serologic prophylactic agent for tetanus, and that as a result of the surgical advances of the last fifty years, gas gangrene is less frequent than in the prebacteriologic days.

We cannot dismiss anthrax so readily; however, it is worthy of note that although anthrax is almost a world-wide disease, nevertheless anthrax infection of gunshot wounds is practically unknown. If gross contamination of battlefields with the organism of anthrax is effected, it is granted that cases of anthrax infection of wounds will occur, and possibly some few cases of infection in individuals who have not been wounded; but when we consider that human epidemic anthrax is unknown during the bacteriologic era, I question if we need fear greater danger from this organism than contamination of wounds.

It will be noted that up to this point we have not discussed the technical difficulties that a military force would have in contaminating a hostile force. The

difficulties in the case of the communicable diseases are so obvious that they need not be mentioned. The epidemiologic factors make the communicable diseases unsuited for offensive military use. The causative organisms are all either short lived when separated from the living tissues or else readily destroyed by ordinary routine sanitary precautions.

We cannot make this statement concerning the highly resistant infections such as tetanus, gas gangrene, and anthrax. These agents are admittedly the most dangerous; but it must be remembered that to be dangerous they must be alive, and that many technical difficulties present themselves when living agents are to be used that are not present when missiles and chemicals are used. Shells can be used to project missiles and chemicals on to an enemy many miles distant, but bacteria cannot be used in this way. No living organism will withstand the temperature generated by an exploding artillery shell. Airplanes may contaminate terrain, but their effect would be quite local and probably less dangerous and less certain than high explosives used in the same way.

It is not maintained that bacterial contamination is impossible. A retreating enemy may hurriedly contaminate the terrain that is to be evacuated. However, it is believed that the use of living organisms in offensive warfare presents technical difficulties that are not generally considered. The contamination that spies and other individuals could effect, using the only really effective agents we have mentioned—the highly resistant, spore-forming organisms that are so dangerous to wounds—would prove too local to be of any value whatsoever.

TOXIC PRODUCTS

The forms of bacterial warfare include not only the possible distribution of living organisms in the force of, an enemy but also the possible use of toxic products derived from bacteria. Certain of our bacterial toxins are the most deadly poisons known. The toxin of the *Bacillus botulinus* is so powerful that instances have been recorded where toxins have been produced so toxic that 0.005 milligram would kill a 250 gram guinea pig. This material, botulinus toxin, is poison for man. It is possibly the most toxic agent known, and will produce the lethal effect in any way that the material is introduced into the animal. If consumed with food, injected into the tissues, or even dropped on the mucous membran or conjunctiva, it is equally deadly.

This must be the material referred to when we read such dramatic statements as the following: "An airplane can carry sufficient toxins to destroy an entire city." Such statements have an element of truth in them. In fact, they are conservative. An airplane could carry enough of the botulinus toxin to destroy every living man in the world *if* administration of the toxin was as simple a process as production and transportation.

There were over one hundred billion bullets manufactured during the World War—enough to kill the entire world population fifty times; but a few of us are still alive. It is easy to calculate the lethal (fatal) dose of a toxic agent; but do not think it is so easy to figure on the casualty-producing power of a military weapon.

The hostile aviator will not be received with a welcome, nor can he expect to land at an air field near any large city and find the entire population lined up ready to accept the carefully measured lethal dose of botulinus toxin.

The release of tremendous quantities of botulinus toxin over a large city may produce human casualties; however, the extent of the damage might be only the wholesale destruction of rodents, sparrows, and possibly numerous cats and dogs —not such a serious loss in time of war. It is difficult to evaluate properly the possible effects of the bacterial toxins. Certainly such statements as an airplane destroying an entire city with toxins is ridiculous; but they may have a value comparable to chemical agents, with this great disadvantage, however: bacterial toxins are readily destroyed by heat; therefore, like bacteria, they are unsuited for use in shells.

ANIMAL DISEASES

The use of living organisms to produce disease in livestock, such as horses and mules needed for transportation of Army equipment and supplies, has been mentioned as a possible form of bacterial warfare. It is believed that the difficulties here are quite similar to those mentioned for diseases attacking man, with this great advantage to the defense that the veterinary officer will have in controlling epidemics. The veterinary officer can destroy any animal or group that he considers a menace to the health of the animals in the Army. The medical officer cannot take such steps to control epidemics that threaten human populations.

If we expand the term bacterial warfare to embrace such phases of biologic warfare as will include the agricultural pests, then an additional factor to consider is the fact that spies, and possibly hostile aviators, might inoculate growing crops with such pests as the boll weevil, the corn borer, the Mediterranean fruit fly, and like destructive agents. These agents in most instances, however, take so long to invade sufficient terrain to be effective in destroying crops that their value in actually overcoming the resistance of a foe is questionable. They take several years to advance over a large area, and might prove an economic problem years after the war has been completed; therefore, they violate one of the fundamental ideas in warfare, since they would interfere with the ability of the conquered nation to pay the victors for the beating they had received.

CONCLUSIONS

It is believed that it has been shown that the development of implements of warfare represents an evolution based on the gradual application of the improving mind of man. The one factor of importance in this development has been effectiveness. It has been a question of the good mind versus the strong back; of the thinker verses the lifter. It is believed that the future of warfare will be based on the same principles. It is, therefore, apparent that the question of whether chemical munitions will be used or not, and whether bacterial warfare will be used or not, will depend on their practicability rather than on the sentimental reactions of pacifists.

I consider that it is highly questionable if biologic agents are suited for warfare. Certainly at the present time practically insurmountable technical difficulties prevent the use of biologic agents as effective weapons of warfare.

CARING FOR THE NAVY'S HEALTH*

CAPTAIN LUCIUS W. JOHNSON, M.C., U. S. NAVY

FEW people had any conception of the vast, intricate organization that made up the Medical Department of the United States Navy before the blooming of the national emergency. Since that time the demands of global war have increased its scope many times, and this growth has occurred with such rapidity that one has more and more difficulty in realizing its size and complexity.

Medical service is provided on shore at recruiting stations, training stations, naval air bases, industrial navy yards, and many other activities. At sea, every ship, large or small, has its medical facilities in accordance with its prospective needs. Numerous bases in our island possessions and on foreign shores, and expeditions sent out to establish new bases, must have adequate combat medical organizations. Procurement and distribution of personnel and material to supply these requirements become a task of great magnitude. It must be remembered that the Navy includes the United States Marine Corps and, for the duration of the war, many activities of the United States Coast Guard.

The policies of the Medical Department are based on the realization that the bluejacket is the essential ingredient in Uncle Sam's struggle to survive. No matter how perfect the guns and the machines may be, the man who operates them is more important. A trained naval man is the result of a long and expensive course of selection and instruction. If one is lost to the service by sickness or injury, it is a serious matter, for his place can be filled only by another who has gone through the same long preparation. Nothing should be denied that will aid in preventing the loss of the services of a single man.

To care for the sick is an important function of the naval doctor, but he has as equal duty to prevent illness and injury. The mission of the Medical Department used to be expressed thus: "To keep as many men at as many guns as many days as possible." Wartime speed-up has now shortened this to: "Keep 'em well." Special effort is made to prepare the doctors entering the naval service for this important phase of their duties. Many have been sent to take special courses in public health work and industrial medicine at some of our leading medical colleges. Others have gone to the Naval Medical School for instruction in naval hygiene, tropical medicine, and other essential subjects.

ACTIVITIES ON SHORE

It is commonly believed that the hazards of the sea and of combat with the enemy are the principal dangers that confront the man of the Navy, but this is

*For reasons that the reader will understand, definite statements concerning the size and location of naval activities have been avoided.

The ideas and opinions here expressed are the private views of the writer and are not to be regarded as the policy of any government department.

All photographs used in this article are reproduced with permission of naval censor.

far from true. The accidents and diseases of the civil community have provided the greatest menace to his welfare. For example, during the last few years motor vehicle accidents on shore have been the greatest cause of death of Navy men, far exceeding drowning. There are many indications that this trend will be changed for the duration of the war.

Transplanting young men from their home towns to new communities for training exposes them to contagious diseases against which they have little immunity. It has been found good practice not to send them aboard naval ships until they have passed a few weeks under medical observation.

The bluejacket's first contact with the doctor is at the recruiting station, where he undergoes his preliminary physical examination. From then on, throughout his naval career, he is under medical surveillance. Forty years ago, Gatewood expressed the opinion that the Navy should keep its very best doctors on duty at the recruiting stations, so that they could detect men having latent defects or diseases, and so exclude them from the service. By doing this, he wrote, the dangers of syphilis and other transmissible diseases could be greatly reduced. The difficulties of accomplishing this are obvious, but it still sounds like an excellent idea. Today, the recruit has his blood tested and an x-ray film taken of his chest, while the psychiatric examination takes on increasing importance.

At the training station a careful medical observation of the recruit is made to detect any hidden defects and to discover contagious diseases in their early stages. Here he receives protective inoculations against a number of diseases, and undergoes a rigorous course of physical training which is designed to uncover any concealed weaknesses. His mental reactions are carefully studied to determine whether or not he can be molded to fit into an organization whose prime need is teamwork.

A concise description of the odd number who cannot work with others is contained in Lafcadio Hearn's statement that the Samurai class in Japan had the right and the duty to behead instantly any inferior person whose conduct was "otherwise than expected." We do not yet dispose of men with schizoid tendencies in this summary manner, but we do try to identify them and determine their potentialities, so that we can employ them where they will be most useful and will do the least harm.

Our industrial navy yards have expanded enormously in size, and many of their departments are working night and day. This imposes a greater mental and physical strain on both shop and office workers. New methods and new materials are constantly being introduced, and they bring with them new industrial hazards which, at first, may be imperfectly understood. It is the duty of the medical officers attached to the yard to study these new developments and to find out what can be done to reduce their menace. At mine and net depots, submarine bases, ammunition depots, aviation training stations, and other naval plants the medical man must be on the alert to detect and alleviate harmful industrial conditions.

Medical establishments are provided at all naval and Marine Corps bases. Those at air bases, navy yards, Marine barracks, and training stations are usu-

ally called dispensaries; it requires special authority from Congress to designate one as a naval hospital. Before our entry into the war several of these dispensaries were complete hospitals with as many as 200 beds. Since then there has been a great increase in their size and number. In staff, equipment, and professional standards, naval dispensaries are equal to hospitals of similar size in civil communities. They provide medical care not only for men of the armed services, but also for civilian employees who are injured or become sick while at work.

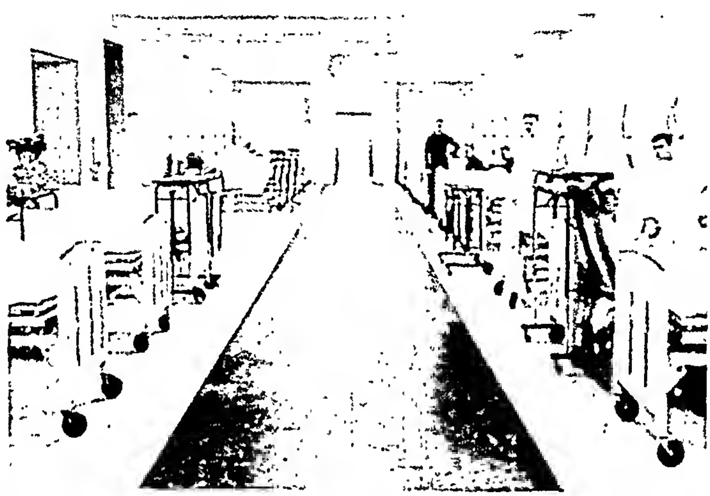

Fig. 1.—One of the wards in a naval hospital. Nursing is done by men of the Hospital Corps, supervised by women of the Navy Nurse Corps.

Naval hospitals are located at strategic points along our coasts, usually near the larger naval bases. Several new ones have been recently built or acquired, and the old ones have been the scene of great activity in the effort to expand them rapidly enough to meet the demands of our augmented Navy. That phase is now nearly completed, and we have time to concentrate on the work of perfecting the equipment and the standards of professional work in our naval hospitals.

Before the present struggle began, hospitals enjoyed an almost complete immunity from hostile attack under the Red Cross flag. In this era of total war they have become special targets, marked for destruction, because loss of hospital facilities has a damaging effect on morale, civil as well as military. The location of most of our naval hospitals, close to large industrial and military establishments, makes them especially vulnerable, and so careful consideration is being given to the need for hospital facilities located farther inland, where the danger of attack would be less. Protection of the existing hospitals is now receiving a great deal of attention. Every necessary step is being taken that will enable them to carry on their work during and after an enemy attack.

ACTIVITIES IN SHIPS AND OVERSEAS

Each of the larger ships of the Navy has its own hospital. Back in the days of Lord Nelson, the increasing weight of armament required that the new

wooden line-of-battle ships be of much heavier construction. This left deep bays on each deck, between the massive timbers. In one of these the hammocks for the sick were slung, and it acquired the name of "sick bay." That term is still used to designate the ship's hospital. A large ship, such as an aircraft carrier, may have as many as 50 to 60 bunks in her sick bay, in addition to an isolation ward, dental clinic, and doctors' offices. Her operating room is as completely equipped as that in a large city hospital. Provision can be made for any necessary operation on any part of the body. On her staff there might be as many as 7 doctors, at least one of whom would be a skilled surgeon. One or more dental officers would form an essential part of the medical staff.

Fig. 2.—A class in chemistry at a Hospital Corps Training School. Many of these men become skilled technicians.

Since there are no accommodations for women on our warships, nursing is done by enlisted men of the Hospital Corps. They are carefully selected from the better-educated recruits, and must have temperaments adapted to the care of sick persons. After their course at the training station is completed, they are sent to Hospital Corps training schools for instruction in their special work. From there they are sent to our larger naval hospitals for a period of practical work in the wards and clinics. Here they are taught by naval doctors and by women of the Navy Nurse Corps. The latter are all graduates of recognized schools of nursing; the Navy does not train any of its nurses.

Many of the men of the Hospital Corps become highly-skilled technicians in the various medical specialties. An index of the success of their course of training is found in the constant demand for navy-trained men when their enlistments expire. Large industrial organizations desire them for male nurses, first-aid

men, and technicians in laboratory, x-ray, or other special work. Throughout the Navy they provide a very satisfactory nursing and technical service.

Smaller ships, such as destroyers, have a man of the Hospital Corps attached to each, while the mother ship of the group has a large sick bay with medical and dental staff, and complete clinical facilities. It is the purpose of the Medical Department to bring its services close to every man of the Navy and Marine Corps, no matter how distant he may be, or how small the unit to which he is attached. One of the important factors in maintaining the morale of small organizations in remote locations is the assurance that a sick or injured man will have adequate medical attendance.

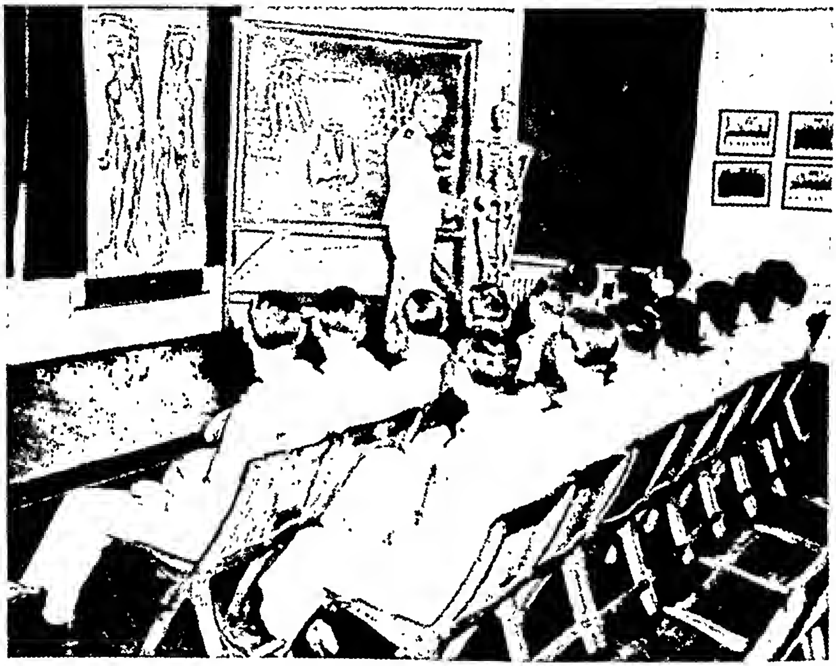

Fig. 3.—Class in anatomy at a Hospital Corps Training School.

Expeditionary forces are an important feature of the Navy's work. The Marine Corps is a unique, amphibious outfit, designed to act as a spearhead that can be advanced with great rapidity over long distances, to seize and hold advanced bases. This highly specialized duty requires the medical organization and equipment to be carefully planned, so that the doctor may be there with his necessary materials at the critical moment. To many medical officers this is the most interesting phase of the Navy's work. Many ingenious plans and gadgets have been devised by various medical officers during their study of the problems of expeditionary duty.

Many new and intricate problems of public health are imposed by the Navy's recent occupation of bases on foreign shores. At several of these, the prevalent diseases of the local people may be a greater danger than any action of the enemy. Problems of food, clothing, and living conditions must be studied, and unsanitary conditions must be corrected before the fighting forces can maintain their highest combat efficiency.

Our Navy is undergoing a precipitate change in character as a result of the lessons of recent months, with the air force becoming the dominant branch. This places on the Medical Department the obligation to develop ways and means of providing medical care under the changing conditions. New hazards and new difficulties are being encountered almost daily, so that an enormous amount of research is required to define the new problems and to find solutions for them. Many medical officers are now under training in the important specialty of aviation medicine, and the aid of some of the ablest scientists in the country has been obtained for research in the medical problems of flight.

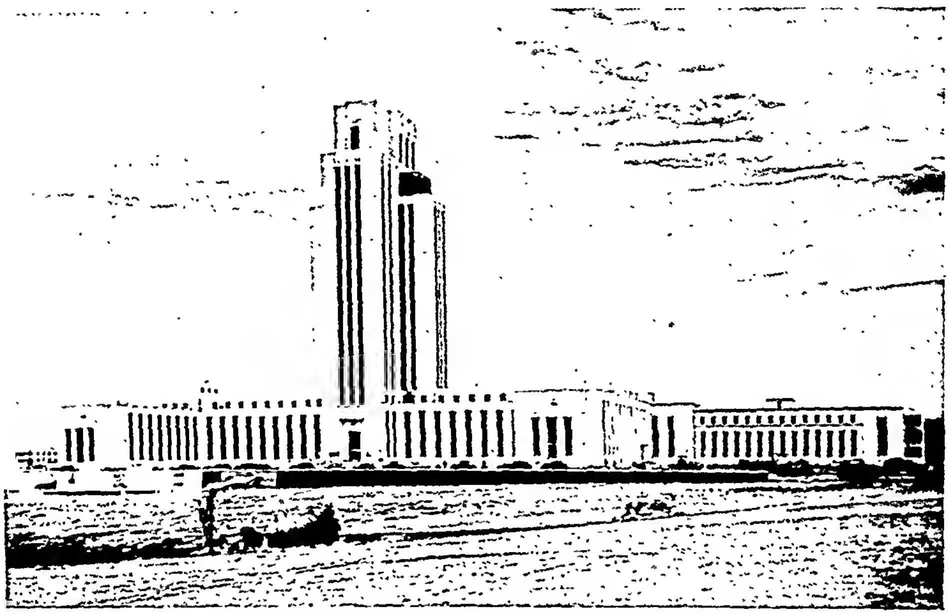

Fig. 4.—The new buildings of the Naval Medical Center, at Bethesda, Maryland, were recently dedicated by President Roosevelt.

NAVAL MEDICAL INSTITUTIONS

First among these is the Naval Medical Center, located in Bethesda, Maryland, a suburb of Washington. The magnificent new buildings which house its many activities have recently been dedicated to their beneficent purpose. The group includes the Naval Hospital, Naval Medical School, Naval Dental School, the research activities, and schools for training technicians in many special branches. The buildings were designed and equipped to equal the facilities of the best hospitals and professional schools throughout the country. Since all medical and dental officers enter the Navy after they have completed their professional education, these schools offer postgraduate courses.

Before the rapid expansion of the Navy began, it was the policy to send newly commissioned medical and dental officers to these schools to learn the ways of the service, and also to receive instruction in several specialities which are of little interest to the general practitioner, but are of vital importance to the naval doctor. These included naval hygiene, tropical medicine, emergency surgery, public health work, and an outline of the problems of diving, aviation, and submarine work.

Development of naval hospitals has been rapid since we entered the war. New ones have been taken over, and the old ones have been greatly enlarged. They are staffed and equipped so that the patients may have everything and every care that may be helpful in their recovery. It is the aim of Admiral McIntire, our Surgeon General, to have the equipment and the professional services in naval hospitals equal to the best that can be found anywhere in the country. Nothing is spared that will aid in accomplishing this purpose.

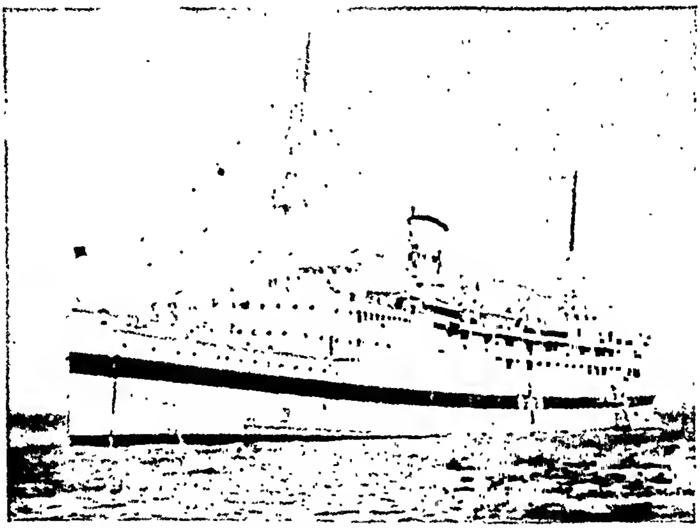

Fig. 5.—U. S. S. Solace, one of the hospital ships that accompany the fleet. She was commissioned in August, 1941.

Floating hospitals perform an important function in our Navy. If you can imagine a force of 50 or more ships, with 45,000 men, shoving off from its base for prolonged operations in distant waters, you will realize that it requires hospital facilities at least equal to those of an industrial city of that many people. Hospital ships have the staffs and equipment that will provide complete service in all the clinical specialties, and they are also prepared to act as public health laboratories. They serve the fleets at their bases, and they are able to accompany them when they proceed on their distant missions.

Much attention has recently been devoted to mobile hospitals, and they have proved their value in several combat areas. They are hospitals of several hundred beds, designed, staffed, and equipped so that they may be quickly moved by land, sea, or air, and rapidly set up when the new location is reached. Their purpose is to serve advanced bases, and to furnish hospital facilities as soon as possible after an expedition to a remote area has landed. If required, they can send off smaller units to serve subsidiary bases. An infinite variety of methods can be employed to adapt them to the needs of special areas, or to different types of military organizations.

MEDICAL DEPARTMENT PERSONNEL

For many years the Navy obtained its medical officers by competitive examination of men from class A medical schools. More recently, selected graduates

were admitted for intern training in naval hospitals. Since the emergency dawned, reserve medical officers have been called to active duty so rapidly that they now greatly outnumber those of the regular Navy. The medical officers of the Naval Reserve were carefully selected men, outstanding members of the profession in communities all over the country. When the call to duty came, they gave up their practices, severed their profitable civilian connections, and devoted their talents to serving the needs of Navy men. This influx of new men with new ideas and new talents has been of great value to the service, for many were teachers and research workers of unusual ability. It can be safely stated that nowhere in the country is there better professional service than that provided for the bluejacket in the average naval hospital.

Fig. 6.—Medical ward in U. S. S. Relief, hospital ship, which was commissioned in 1920.

In our naval hospitals the medical officers carry a gradually increasing load of administrative responsibility throughout their careers. The young medical officer in charge of a ward is responsible for the cleanliness and good discipline of his area, as well as for the professional care of his patients. This helps to develop rivalry and a sense of pride in the appearance and functioning of the whole institution. By the time a man becomes executive or commanding officer of a hospital, he is thoroughly familiar with most of the details of the uniform system of administration. The administrative system is constantly kept up to date by adopting the best methods observed in civil hospitals.

Dentists are appreciated as very valuable members of the Medical Department team. In the old days of the Navy, if a man had enough teeth to pass the physical examination for enlistment, he received no further official attention. It is different now. Every effort is made to put the teeth of every man in first-class condition during his period of training, and to maintain them in that con-

dition throughout his time in the service. An infinite amount of suffering is thus prevented.

The dentist in the Navy performs many other important functions. He is usually called upon to collaborate in the treatment of fractures about the face and jaws, and frequently assists in operations in this field. His special training in regional anesthesia enables him to give the general surgeon much-needed aid in many cases. During the pioneer work with Naval Mobile Base Hospital No. 1, the dental officer was of invaluable assistance and performed with enthusiasm many duties far outside his professional field. At Pearl Harbor and other combat areas, the first-aid work done by the dental officers has received the highest praise. Reserve dental officers, like their medical colleagues, have reported for active duty in great numbers, and are gladly welcomed as an important addition to the staffs of naval activities.

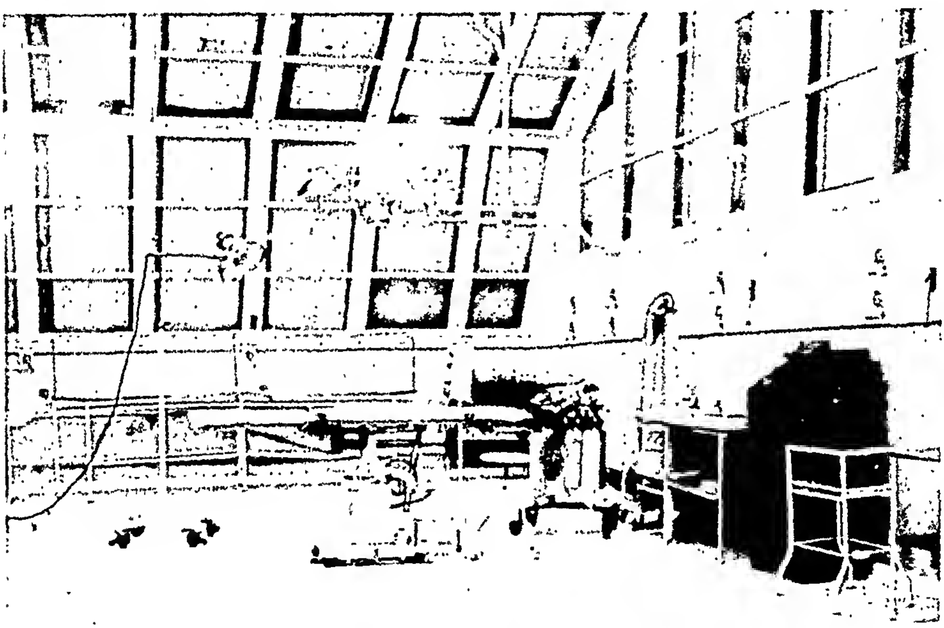

Fig. 7.—Port side of the operating room, U. S. S. Relief. Operations can be done while at sea, just the same as in port.

The Navy Nurse Corps is composed of female graduates of recognized nursing schools, who undergo careful scrutiny and selection before being appointed. The reserve nurses were organized with the aid of the American Red Cross. In our naval hospitals these women maintain a very high standard of nursing service. They also perform a very valuable function in training the men of the Hospital Corps. The obligation of our naval hospitals to provide well-trained corpsmen for duty on ships and at remote bases is second in importance only to the care of patients. A bill has recently been passed and approved which gives to nurses in the Navy increased pay and a definite status as officers. This is a well-merited recognition of their valuable service to the Navy.

Pharmacists are men who have served for many years in the Hospital Corps. They have long been restricted to warrant grades, but recently authority has

been given for their advancement to commissioned ranks. Their duties have little to do with pharmacy, but are more concerned with property and accounting, commissary, and personnel work. They are invaluable administrative aids, and no commanding officer could wish for a greater blessing than to have two or three old-time naval pharmacists on his staff.

Men of the Hospital Corps have frequently been spoken of as the most versatile men to be found anywhere, and there is ample justification for this. They are trained in nursing and the technical specialties of the medical field. Service with the Marines teaches them the use of tools and weapons, and develops their ability to take care of themselves in the field under all sorts of conditions. Duty on board ship gives them some knowledge of many mechanical trades, as well as an understanding of nautical life. Clerical work and accounting are also a part of their training. The result of all this is an alert, well-disciplined man, who is fitted to make his way in life, and to be a useful member of any organization.

An outline has been presented of the means by which the Medical Department of the Navy acts to perserve the health of its men and to care for those who are sick or injured. A severe test of the efficiency of the organization was provided by the surprise attack at Pearl Harbor, December, 1941. It is gratifying to be able to state that the preparations were found to be adequate. The Naval Hospital, the hospital ship, and Naval Mobile Base Hospital No. 2 were able to care for all the naval casualties without having to call for outside aid. Disinterested observers, who later examined the injured, spoke with praise of their excellent condition. They stated that never before had a large number of seriously-injured persons made such favorable progress.

If the general public, and especially the relatives and sweethearts of men in the Navy, could know what complete and elaborate preparations are made for conserving their health, it would be a great solace to them. Uncle Sam neglects nothing that will aid in preserving and restoring the health of the men of his Navy.

THE DEFINITION AND SCOPE OF NAUTICAL MEDICINE

CAPTAIN LOUIS H. RODDIS, M.C., U. S. NAVY

MOST civilian medical men realize that nautical medicine is a specialty which is as definite and distinct as the other professional medical specialties and that a specialist in naval medicine occupies a particular field as much as does a specialist in pediatrics or surgery.

The terms "nautical," "maritime," and "naval medicine" are three terms which are often considered as synomons. This is perhaps true of nautical and maritime medicine. Naval medicine, however, has a somewhat different meaning. Nautical or maritime medicine may be defined as that branch of medical science which has to do with the prevention and treatment of diseases and injuries peculiar to maritime or nautical life. Naval medicine may be defined as that branch of nautical medicine which is particularly concerned with diseases and injuries incident to both life at sea and naval warfare.

One of the subjects of special importance to the seagoing doctor is that of naval hygiene, which includes problems connected with ventilation; air conditioning; heating; waste disposal on board surface ships, submarines, and closed cabin aircraft. Other subjects of study are physical changes in relation to rapid changes in climate, an important matter in maritime medicine, where a man may be in a polar latitude one week and the temperate zone or tropics a short time later; the question of water supply at sea; production of fresh water from sea water or from the moisture of the air; bacteriology of the air at sea and the bacteriology of sea water; the care of the sick and injured aboard ship; the structural feature of the ships in relation to health; the control of disease vectors aboard ship; the study of epidemiology as affected by living conditions aboard ship and the prevention of diseases under conditions of shipboard life; the study of such a particularly nautical disease as seasickness and injuries from special nautical hazards, such as falls from masts and down hatches, injuries from handling boats, anchors, and similar accidents of nautical life; wounds inflicted by fish and marine animals; inspection and preservation of food for ocean voyages; proper rations, including special emergency rations for planes, boats, and submarines; and the transportation of the sick and wounded aboard ship, from ship to ship, and from ship to shore.

To such problems as these are added additional ones which may be considered as peculiar to navies and pertaining to naval medicine. Such are the physical standards of physical examinations for entrance into the naval service; the caring for wounded in battle and after battle; the disposition of battle dead; the employment of ambulances and hospital ships and of hospital and ambulance planes; the study of first-aid materials for the individual soldier and sailor; the tactical employment of medical troops with expeditionary forces and landing parties; the treatment of gas casualties; postgraduate training of med-

ical officers and the training of hospital corpsmen and technicians; the maintenance of naval hospitals and naval medical supply depots; the obtaining of drugs and medical and surgical supplies and equipment for use on ships and at naval hospitals; the disposition of cases with permanent disabilities and pensions; the caring for the tubercular and the insane of the Navy; the questions of naval medical history and of naval medical organization and administration; the uniforms and insignia of the medical department of navies; the practice of pharmacy and dentistry in navies and of the utilization of female nurses in naval establishments. All these represent problems and fields in naval medicine, and the naval medical officer must be cognizant of them and know something about them. Training and experience are needed to obtain this knowledge just as in other specialist branches of medicine.

The naval medical officer must be an excellent general practitioner. Often he is in isolated places or the only medical men on a ship in the middle of a large ocean. The medical problems of the men and officers of that ship must be solved by him and him alone. He cannot turn to a specialist or refer a case to a surgeon, an eye, ear, nose, and throat specialist, or a dermatologist just across the street. He must deal with the case himself. I do not mean by this that specialism is not needed in the Navy. As a matter of fact, every specialty must be represented and in the hospitals, and places where definitive treatment can be given specialists in every specialty must be available. I wish, however, to emphasize the point that the naval surgeon must be a good general practitioner first of all, with some definite knowledge of naval medicine. It is said that the specialty of the general practitioner in civil life is obstetrics. I would say that the specialty of the naval surgeon is naval medicine and that both preventive medicine and traumatic surgery form essential features of his specialty.

The versatility of the naval surgeon and the men of ability which his specialty has attracted is shown in the history of nautical medicine. Many of the greatest names in medicine and science have come from the ranks of naval surgeons: James Lind, Sir Gilbert Blane, Linnaeus, Darwin, and Huxley were naval surgeons. The founders of tropical medicine were naval surgeons. Even the surgeon of a crew of buccaneers is known to every medical man today who prescribes Dover's powder. The history of medicine, indeed, owes much to the seagoing medical man.

ADAPTATION OF TECHNICIAN INSTRUCTION TO THE MILITARY EMERGENCY*

MAJOR JACK W. LOVE, M.C., CAPTAIN I. ROTHSTEIN, M.C., AND FIRST LIEUT. J. CUBEL, M.A.C.

CONSIDERABLE interest has been shown recently in the type of training given to enlisted men in the United States Army to equip them to work as laboratory technicians. This interest, apparently, has been stimulated by the realization that we have only a period of twelve weeks in which to prepare these students to assume the many responsibilities of a laboratory technician. It is our purpose to outline the working schedule of training, and we trust that inspection of it will indicate the scope, objective, and methods of instruction used in this course.

The Laboratory Section of the School for Medical Department Technicians has a teaching staff of three full-time officer instructors, one staff sergeant, one sergeant, and three enlisted specialists who act as assistant instructors. As part-time assistant instructors there are other more technically trained specialists who contribute their services during certain periods of the course. The technical background of the staff has been largely acquired in the field of clinical pathology, including the various specialties.

As the training schedule is unfolded, one will readily see that in order to cover the various subjects within the three-month period allowed for this course, there must be a sacrifice of either the formal didactic lectures or the practical "bench work" training. Consequently, in order to have the student derive the utmost from the course, it is so arranged that there is a minimum of lectures; these consist of outlining the particular work to be covered for that day, stressing the salient features and placing emphasis on the more important aspects involved in the performance of the test. The student's interest and proficiency are maintained at a high level by occasionally introducing the clinical application and interpretation of the routine procedure.

In order to fit this course into a period of twelve weeks, the hours of instruction are from 8:00 A.M. to 4:00 P.M., with an hour for lunch at noon. Saturday afternoons and Sundays are given as rest periods, and extra time in the laboratory at night is discouraged except for those students who cannot keep up this rapid pace. This results in a total of 460 hours of training, with the allotment as follows:

*From the Laboratory Section of the School for Medical Department Technicians, Army Medical School, Washington, D. C.

a. Basic Technique	57 hours
b. Hematology	60 hours
c. Parasitology	57 hours
d. Bacteriology	108 hours
e. Histologic Technique	48 hours
f. Chemistry	90 hours
g. Serology	36 hours
h. Advanced Hematology	4 hours
	460 hours

Tables I-III show the daily program divided into three four-week periods following in direct sequence.

Basic Technique.—As this subject implies, each student is instructed in the simpler routine laboratory procedures which are essential in the maintenance and care of supplies and equipment used in clinical pathology. The student is taught to clean glassware properly and to acquaint himself with the various methods of sterilization. He is taught the preparation of stains and solutions, the simpler technique of inoculating solid and liquid media, the transferring of cultures, staining of bacteria, and the making of the so-called "wet" preparations for study. Here the practical "bench work" method of instruction consists of allowing each student to perform this work under proper and adequate supervision.

Hematology.—The object in this part of the course is to train the student to perform a simple blood count with accuracy. The expression "simple blood count" includes the hemoglobin determination, the erythrocyte and leucocyte counts, and the differential white cell tabulation. In regard to other hematological procedures, such as the platelet count, reticulocyte count, peroxidase differential stain, bleeding and coagulation times, only a minimum amount of time and instruction are given in order to give the student merely an insight into these procedures so that each can be performed under supervision. In the second four-week period, four hours of instruction are given in advanced hematology. This time is devoted to demonstrations of the various blood disorders in conjunction with enough didactic instruction to orient the student with regard to the important blood disorders and to help him realize the necessity of assistance from the laboratory director when abnormal cells are encountered during the performance of a simple blood count.

Serology.—The beginning part of this subject is devoted to both demonstration and practical application of venipuncture technique, of the separation of sera from blood specimens, and of setting up both blood typing and crossmatching tests along with their interpretation. The more detailed serologic procedures consist of repeatedly performing the standard and quantitative Kahn tests for the diagnosis of syphilis. In addition, the student is taught to prepare colloidal gold solution and to perform several colloidal gold tests on spinal fluids. The Kolmer complement fixation test for syphilis is also demonstrated.

Histologic Technique.—In this course each student is taught the proper care of the equipment used in the preparation of tissue for histologic examination; this includes the care and sharpening of the microtome knife. Instruction is given in tissue fixation and embedding, and sectioning of tissue with both the paraffin and frozen section methods. In the more advanced part of this train-

FIRST FOUR-WEEK PERIOD

LABORATORY TECHNICIAN TRAINING—S.M.D.T.

8-12 A.M.	*1st Day* Hematology Hemoglobin determination Technique of finger puncture Practical—application of above	*2nd Day* Hematology White blood cells Blood smears, staining, differential count Practical—application of above	*3rd Day* Hematology Errors in differential counts Errors in hemoglobin determination Practical—differentials	*4th Day* Hematology Blood cell counts Calculation of red and White cells Practical—complete blood count	*5th Day* Hematology Errors in red and white cell counts Practical—two complete blood counts	*6th Day* Examination in Basic Training.
1-4 P.M.	Basic Training Outline of course Laboratory rules Care of equipment	Basic Training Cleaning glassware Cleaning—Pipettes, syringes needles, etc.	Basic Training Plugging glassware Wrapping glassware Cleaning new glass	Basic Training Use of thermometer Fahrenheit scale Centigrade scale	Basic Training Glass bending Glass cutting Capillary pipettes·	
8-12 A.M.	*7th Day* Hematology Review—blood counts and calculations Practical—two complete blood counts—reports	*8th Day* Hematology Blood platelets determination importance Practical—blood platelet determination	*9th Day* Hematology Errors in platelet determination Practical—blood count, differential, platelet determination	*10th Day* Hematology Reticulocyte Determination, supra vital staining Practical—reticulocyte Determination, calculation reports	*11th Day* Hematology Errors in reticulocyte counts—review Practical examination on complete blood counts	*12th Day* Examination in Basic Training
1-4 P.M.	Basic Training Sterilization of tongue depressors, throat swabs	Basic Training Use and care of laboratory animals Inoculation of above	Basic Training Elementary chemistry Symbols, elements, compounds Use of balance	Basic Training Solutions—saturated, dilute and normal preparation of solutions	Basic Training Culture media—preparation, adjustment of reaction, storage	

8-12 A.M.	*13th Day* Hematology Errors in examinations Abnormal red cells Practical—blood counts with cautions against errors made in examination	*14th Day* Hematology Peroxidase reaction Use and performance Method of reporting Practical—application of peroxidase reaction	*15th Day* Hematology Coagulation time Bleeding time Practical—application of above	*16th Day* Hematology Review of high points of complete course Practical—review of blood study procedures	*17th Day* Hematology Final examination Practical—W.B.C., R.B.C., color index, hemoglobin determination, and differential	*18th Day* Examination in Basic Training
1-4 P.M.	Basic Training Preparation of media, infusion broth, extract agar, E.M.B. plates	Basic Training Prepare blood agar slants and blood agar plates	Basic Training Demonstration of motile and non-motile bacteria Hanging drop and wet preparations	Basic Training Staining—Gram's stain Loeffler's stain Preparation of dyes for stains	Basic Training Practice in staining Bacteria using Gram's stain Bacteria of sputum, feces	
8-12 A.M.	*19th Day* Chemistry Urine collection constituents of urine Practical—physical and chemical examination	*20th Day* Chemistry Organized and unorganized sediments in urine Practical—microscopic examination of urine	*21st Day* Chemistry Importance of routine urinalysis Practical—complete urinalysis	*22nd Day* Helminthology Classification of worms Life cycles and habitat Practical—examination of unknown feces for eggs	*23rd Day* Helminthology Wet preparations Practical—examination of unknown feces	*24th Day* Final examination in Basic Training Helminthology continued
1-4 P.M.	Basic Training Inoculation of Media Pure cultures supplied	Basic Training Isolation of pure cultures of bacteria from mixed cultures Morphological and cultural characteristics	Basic Training Collecting of specimens and preparation for shipment Practical—application of above	Serology Venipuncture Use of necessary instruments Practical—each man does a venipuncture	Serology Blood typing—importance, method, classification Practical—application of above	

TABLE II

SECOND FOUR-WEEK PERIOD

LABORATORY TECHNICIAN TRAINING—S.M.D.T.

8-9 A.M.	*1st Day* Histology General introduction Fixing fresh animal tissue	*2nd Day* Histology Tissue fixing Introduction to staining eosin, etc.	*3rd Day* Histology Further work with eosin and hematoxylin	*4th Day* Histology Paraffin Embedding, further fixing and staining	*5th Day* Histology Paraffin Embedding and further staining	*6th Day* Histology Paraffin embedding and further staining
9-12 A.M.	Helminthology Review—charts and slides, etc. Practical—examine three unknown feces	Parasitology Characteristics of amebae, importance Practical—*E. coli*, *E. histolytica*	Parasitology Examine feces with cysts Examine cultures with trophozoites	Parasitology Examination—feces containing helminth eggs and amebic cysts	Parasitology Blood and tissue flagellates—*giardia Trichomonas*, *Leishmania*	Parasitology Malaria—life cycle, importance, *P. virax* Practical—examine slides
1-4 P.M.	Serology Cross matching Blood transfusion Practical—blood typing, cross matching	Serology Serological tests Care of glassware Practical—wash glassware	Serology Kahn test, antigen reagents, technique Practical—run a Kahn test	Serology Examination—venipuncture, blood typing, cross matching	Serology Serological forms Shipment of specimens Practical—each man will run 6 Kahn tests	
8-9 A.M.	*7th Day* Histology Further embedding and staining Introduction to decalcification	*8th Day* Histology Embedding, staining, and decalcification	*9th Day* Histology Paraffin embedding, decalcification Study of animal tissues	*10th Day* Histology Introduction to celloidin method Further work in decalcification	*11th Day* Histology Further work in study of animal tissues Further work in the celloidin method	*12th Day* Histology Further work in celloidin embedding, tissue study, paraffin embedding
9-12 A.M.	Parasitology Malaria—compare *P. Vivax* with *P. Malariae* Practical—examine slides of *P. Malariae*	Parasitology Malaria—*P. falciparum*, importance Practical—examine slides of *P. falciparum*	Parasitology Review—all types of malaria with unknown slides Demonstration set up	Parasitology Entomology—roles played by insects, mosquito Practical—study anatomy of mosquito	Parasitology Conclude study of mosquitoes started the previous day	Parasitology Fleas, ticks, lice, bedbugs, etc., medical importance Practical—study set up exhibit

1-4 P.M.	Serology Spinal fluid Kahn Quantitative Qualitative Practical—run a spinal fluid Kahn test	Serology Colloidal gold preparation Practical—each man will run two colloidal gold tests on spinal fluid	Serology Read test set up previous day—report Demonstrations in Serology Department	Serology Review complement fixation test Practical—each man will read 15 colloidal gold tests	Serology Final written examination in serology	
8-9 A.M.	*13th Day* Histology Further work in celloidin embedding Cutting paraffin sections	*14th Day* Histology Celloidin method Cutting of paraffin sections	*15th Day* Histology Cutting of paraffin sections and further tissue study	*16th Day* Histology Introduction to cutting and staining frozen sections	*17th Day* Histology Cutting and staining frozen sections	*18th Day* Histology Cutting and staining frozen sections
9-12 A.M.	Parasitology Study various types of flies—their medical importance Practical—study fly exhibit	Parasitology Review of entire course Practical—examine unknown stool and blood specimens	Parasitology Final examination covering unknown stools, slides, and demonstration	Bacteriology Classification of bacteria—*Staphylococcus albus* and *aureus* Practical—streak blood plates, make Gram stain	Bacteriology Examine plates made previous day, cultural characteristics Streak blood plates with *Staph. pyogenes* and *Staph. salivarius*	Bacteriology Examine plates made previous day Characteristic Gram's stain of organisms
1-4 P.M.	Hematology Anemias of all types Polycythemia Purpuric—hemorrhagic diseases	Hematology Leucemia—acute and chronic types Bone marrow studies, etc.	Chemistry Quantitative examination of urine	Chemistry Quantitative examination of urine	Chemistry Quantitative examination of urine	
8-9 A.M.	*19th Day* Histology Introduction to Giemsa's staining for bacteria	*20th Day* Histology Further work with Giemsa's stain for bacteria	*21st Day* Histology Cutting and staining celloidin sections	*22nd Day* Histology Cutting and staining celloidin sections	*23rd Day* Histology Practical examination Identification of tissues	*24th Day* Histology Written examination on technique procedures
9-12 A.M.	Bacteriolgy Technique of blood cultures Practical—make a blood culture	Bacteriology *D. Pneumoniae* Identification Inoculation of plates Neufeld reaction	Bacteriology Study *D. pneumoniae* Bile solubility test Examine blood plates for type of colony	Bacteriology Genus *Neisseria* Inoculation, Gram's stain, characteristics Diagnosis	Bacteriology Examine plates of Neisseria organisms Examine smears from acute cases	Bacteriology *N. intracellularis* characteristics Polyvalent and type agglutination test

9-12 A.M.	Bacteriology Gram-negative enteric bacilli Inoculation of *E. typhosa*, para A and para B	Bacteriology Identification of pathogenic enteric bacilli—procedure	Bacteriology Further work with enteric bacilli inoculation cultures	Bacteriology Further work with enteric bacilli Examine cultures	Bacteriology Further work with enteric bacilli Agglutination tests	Bacteriology Food poisoning Read agglutination tests previously set up

1-4 P.M.	Blood Chemistry Urea nitrogen, uric acid, creatinine determinations	Blood Chemistry Urea clearance Collection of specimens	Blood Chemistry Urea clearance determination	Blood Chemistry Glucose tolerance test and determination	Blood Chemistry Sulfonamide chemistry Sulfanilamide determination	
8-9 A.M.	*13th Day* Histopathology Iron hematoxylin stain for fibrous tissue	*14th Day* Histopathology Iron hematoxylin Stain for fibrous tissue	*15th Day* Histopathology Weigert's stain for elastic tissues	*16th Day* Histopathology Mallory's phosphotungstic stain for fibrous tissue	*17th Day* Histopathology Mallory's phosphotungstic stain for fibrous tissue	*18th Day* Histopathology Mallory's phosphotungstic stain for fibrous tissue
9-12 A.M.	Bacteriology Prepare antigens Set up agglutination tests made with above antigen Examination	Bacteriology *Vibrio comma* Inoculation of non-pathogenic *V. Comma*	Bacteriology Further work with *V. Comma*—genus Brucella	Bacteriology Spore-forming bacteria genus *bacillus* Aerobic culture methods	Bacteriology Spore-forming bacteria genus *Clostridium* motility tests	Bacteriology Spirochetes—*Treponema*, *Leptospira* and *C. borrelia* (Vincent's angina)
1-4 P.M.	Blood Chemistry Calcium and phosphorus determinations	Blood Chemistry Liver function test	Blood Chemistry Carbon dioxide and carbon monoxide determination	Blood Chemistry Phosphatase determination	Blood Chemistry Cholesterol determination	
8-9 A.M.	*19th Day* Histopathology Stains for hemosiderin	*20th Day* Histopathology Stains for hemosiderin	*21st Day* Histopathology Silver impregnation for syphilis	*22nd Day* Histopathology Final examination	*23rd Day* Histopathology Clean up the laboratory	*24th Day* Graduation Exercises
9-12 A.M.	Bacteriology *Corynebacterium* *C. diphtheriae* *C. xerosis*, etc.	Bacteriology Virulence test for *C. diphtheriae*	Bacteriology Mycobacterium Ziehl-Neelsen staining	Bacteriology *Mycobacterium* concentration of specimens	Bacteriology Yeasts and molds Final examination	
1-4 P.M.	Blood chemistry Serum protein determination	Blood Chemistry Clean apparatus for the final examination	Blood Chemistry Final examination Practical	Blood Chemistry Clean up laboratory Prepare solutions	Toxicology Lecture with demonstrations	

ing, the student is taught to use various stains, with their respective indications and value, although emphasis is placed on the routine hematoxylin eosin and Masson trichrome stain techniques. The hematoxylin eosin stain is used on tissues that are carried through the entire routine by each student. Naturally, in teaching tissue selectivity, a few essentials of histology are included so that the student may, to some extent, recognize the different tissues under the microscope.

Parasitology.—Throughout this entire course practical "bench work" is stressed, and the only lectures given are to guide the student in his routine work and to point out the more important features used in the identification of the various parasites. The course starts with the study of the various helminth ova, using both fixed preparations and stool specimens; then gradually the more detailed studies are added, which include identification of the malarial parasites, insects, and arthropods. Each student is equipped with a loan set of slides of fixed preparations, and considerable time is devoted to the study and practical examination of these slides.

Bacteriology.—In this course each student is familiarized with the practical aspects of bacteriologic technique, especially that part which will enable him to isolate and identify tentatively the various bacteria of medical importance. During the six weeks of three-hour periods, each of the genera is studied, with emphasis being placed on the more important species. In dealing with the more common pathogenic bacteria, a morphologic and cultural study is performed, and where indicated, differential media, biochemical, serologic and animal tests are used. The special procedures covered during this course include the performance of blood cultures, pneumococcus and meningococcus typing, water and milk analysis, agglutination tests, anaerobic culture methods, and the dark-field technique.

Chemistry.—The student is first taught the simple and practical fundamentals of chemistry. With this background, the course embraces the various phases of a routine urinalysis, including the physical, chemical, and microscopic examination, using normal and abnormal urine samples. Practical instruction is then given in titration, normal solution preparation and both are utilized in the performance of a fractional gastric analysis. The final four-week schedule has each afternoon devoted to metabolic chemistry. A large part of this scheduled time is used in the actual performance of the various metabolic determinations requested of a well-organized chemical section of a medical laboratory. In this more detailed portion of the course, it is only natural to include some of the practical working theories, but these are only dealt with from their useful and practical aspects.

Tables IV, V, VI, and VII represent graphically an analysis of twelve successive classes of students trained during the first year of this course (Laboratory Section, S.M.D.T.) of the Army Medical School. Table IV reveals that half of the students admitted were college students, college graduates, or postgraduate students. Less than 10 per cent of the students admitted had only a grade school education. Table V shows that while the number of students does not allow for statistical scrutiny, certain generalizations may be made. The average

TABLE IV

TABLE VII

RATINGS OF TECHNICIANS	NUMBER	AVERAGE GRADE (%)
T-1 Master technician	0	0
T-2 Expert technician	1	98
T-3 Senior technician	122	93
T-4 Technician	72	87
T-5 Junior technician	10	82
Students dismissed as T-5	3	70
Students dismissed no rating	48	60
Students transferred T-5	1	92
Students transferred no rating	12	85
Total	269	

grades of the students seem to vary directly with the degree of previous education. In regard to previous laboratory experience, this factor is of considerably less significance than the amount of education in determining the progress of the student in our laboratory course. Table VI is shown merely for the sake of completeness and, since it includes among the nongraduates, students who were dropped due to illness, no conclusions will be drawn. Table VII shows that these latter students did very well up to the time of their transfer. The majority of the students graduated received a Technician 3rd Class or Senior Laboratory Technician qualification on their certificate.

Each of the ratings listed in Table VII denotes certain definite capabilities and qualifications, although it must be remembered that we only recommend the graduates for these ratings. These ratings may be summarized as follows:

MEDICAL LABORATORY TRAINING QUALIFICATIONS*

"*a*. Junior Laboratory Technician, 5th Class: A graduate of the course for laboratory technicians, Army Medical School, or an equivalent course in a civil institution or the equivalent in practical experience, and able to perform the following:

(1) Cleaning and sterilization of laboratory glassware and equipment under direct supervision.

(2) Ordinary routine laboratory procedures, such as urinalysis, blood counts, preparation and staining of slides, and care of cultures.

(3) Care of laboratory animals

(4) Preparation of routine culture media.

b. Laboratory Technician, 4th Class: Qualified as in *a* above, and able to perform the following:

(1) All routine tests on blood, urine, sputum, stools, and pus exudates.

(2) Elementary bacteriology, agglutination and serological tests.

c. Senior Laboratory Technician, 3rd Class: Qualified as in *b* above, and able to perform the following:

(1) Preparation of all stains, solutions, and media.

(2) Routine procedures in any department of a corps area or similar laboratory.

(3) The preservation, preparation, and mounting of pathological materials.

d. Expert Laboratory Technician, 2nd Class: Qualified as in *c* above, and able to perform the following:

(1) Train laboratory technicians in lower grades in the performance of routine laboratory tests.

(2) Assume technical charge of one or more divisions of a corps area laboratory or equivalent.

(3) Carry out, under supervision, more complicated laboratory tests in serology, chemistry, and pathology.

e. Master Laboratory Technician, 1st Class: Qualified as in *d* above, and able to perform the following:

(1) Special ability in one or more laboratory specialties, demonstrated during long and excellent service.

(2) Ability to take charge of any corps area laboratory or equivalent under direct supervision of an officer."

*-MTP 8-1 Medical Department Mobilization Training Program, Medical Field Service School, Carlisle Barracks, Pa., 1940, pages 16-17.

SUMMARY

1. An outline for teaching a laboratory technician course to enlisted men of the United States Army has been presented. This course has been condensed to meet the present emergency. By relying mainly on practical application and demonstration, this entire course is given in the allotted twelve weeks.

2. An analysis of the students graduating during the first twelve months reveals that the final average of grades and individual recommended ratings depend more on their educational background than on previous practical laboratory experience. The majority of students taking this course have been recommended as senior laboratory technicians on the basis of their practical knowledge and ability acquired in this work.

We wish to acknowledge the assistance given by Technical Sergeant A. J. Babalonis in compiling the statistical material.

THE GENERAL MISSION OF MILITARY AVIATION MEDICINE*

BRIGADIER GENERAL DAVID N. W. GRANT, M.C., THE AIR SURGEON, ARMY AIR FORCES

AVIATION is a comparatively new field towards which man has come to direct his energies. At first only a dream, it soon became a reality. Today it is the hobby of thousands, as well as the bread and butter to thousands more. To many it is a curse because it brings fear, destruction and death as an instrument of war. Even under the best conditions it is a calling not without its hazards, for many deaths and broken bones have been left in the wake of its progress, but it has nevertheless advanced rapidly and today can take its place among other occupations as a vocation.

Man has ever been seeking improved methods of transportation, the goal always being increased speed. Each development and improvement of means of travel have presented new medical problems. The development of aviation has been no exception. It has brought with it problems of oxygen want, acceleration, unprecedented demands on the special senses, the nervous system, the heart, and other organs.

World War 1 stimulated the first intensive interest in the medical problems involved in aviation. When the United States entered the War, it benefited greatly by the very unfortunate experiences suffered by the British in the first two and one-half years of that conflict. An analysis of Great Britain's flying casualties during that period showed that of one hundred air fatalities, only two were killed by the enemy, eight deaths resulted from defects in the plane, and ninety were due to deficiencies in the individual, either physical or mental. In those early days virtually no attention was paid to the selection of the individual who was to fly from the medical standpoint. Men were often assigned to aviation duty after they had become unfit for service in the ground arms. The wastage of personnel and material, of course, was enormous.

*Read at the 49th annual meeting of the Association of Military Surgeons of the United States, Louisville, Ky., October 29-November 1, 1941.
Reprinted from The Military Surgeon 90: 281 (March), 1942.

Upon the entry of the United States in the War, the Medical Department was faced with the problem of overcoming all those conditions affecting the physical fitness of the man who was to go in the air. It was at once realized that everyone should not fly, and investigations were immediately begun and have been continued ever since on the problems of selection of flying personnel, and, after their selection, their maintenance in a normal condition.

The general mission of aviation medicine, that of the selection and care of flying personnel is and always has been intimately associated with National Defense. That this mission has been well accomplished is proved by the recent recognition of aviation medicine as a specialty. It is not anticipated that this mission will change, nor is it to be assumed that there will be other than minor difficulties encountered in its accomplishment even when expanded to the present scope of National Defense. *The problem of the moment, therefore, is an orderly expansion of aviation medicine in step with National Defense.* The attending difficulties encountered in any such tremendous expansion are many, but, in a general way, they fall into one of two large groups: First—Problems of personnel. Second—Problems of training.

These problems are tremendous and call for a separate discussion, not within the scope of this paper; rather will I undertake briefly to discuss the general mission of military aviation medicine, that is the selection and care of the military flier, for at this time we are faced with the tremendous problems of securing 30,000 new pilots each year, which calls for the special examination of approximately 120,000 young men. Not only must these men be chosen for their ability to learn to fly, but also from the standpoint of their ability to withstand the stress of operational flying over a long period of time. These figures do not take into account the selection of other crew members, bombardiers, navigators, gunners, and the like, totaling another 100,000.

In selection, the flight surgeon endeavors to select only those individuals for flying training who are most free from real or potential physical and mental abnormalities. The physical examination for flying is more than an objective physical survey. It is an investigation of those bodily and mental attributes, which, by reciprocal action, serve to define the individual as an entity. It has for its object an estimation of his special suitability for a task in a new environment.

Flying subjects man to unfamiliar environmental factors and places under his control a strange and powerful mechanical force which greatly taxes his resources. It creates thereby a new experience which is capable of providing an extraordinary test of his adaptability. The estimate of aptitude for new and specific tasks relies on an evaluation of the individual's entire equipment. It seeks to weigh the potentialities of body and mind and to apply them to the demands of the special situation. It considers native and acquired resources, and computes their utilization. The new task has its origin in the multitudinous needs and desires of man in his peculiar environment. It signifies a new experience, which, found useful and desirable, is retained and perhaps modified for the benefit of the individual and others. It may range in variety from the most simple to the most complex, from the elementary forms of performance to the technical accomplishments developed in the various arts and sciences.

The complexity of the task to the individual is gauged by the degree of stress which it imposes upon his resources. He may have been endowed with sufficient inherent capacity to achieve success, if he so wills, or his capacity may be so limited that achievement is impossible in spite of effort. It is, therefore, obvious that each individual is not qualified by inherent capacity or aptitude to perform the same task with an equal expenditure of endeavor and a like effectiveness.

Aviation is a complex task. It contains the finesse of an art and the exactness of a science. From a military standpoint, it should be performed with the highest degree of efficiency.

The individual for military aviation should be selected with great care. Physical fitness to combat the stresses of flying is not the only requisite. Stability of mental and nervous organization is equally important.

Experience in military aeronautical training has often demonstrated that not every student can meet the requirements of the flying task within the accepted standards. Although he has been physically qualified, is a member of the optimum age group, and has the essential educational background, he may nevertheless fail in adjustment and performance.

It must be remembered that our present physical standards for military flying are based on past experience in matters of efficiency and safety. It is known that some men with physical handicaps, such as having only one leg, or one eye, tuberculosis, or other handicaps, have made excellent pilots. However, immediate efficiency and ultimate economy unquestionably indicate the wisdom of admitting to training only the very best physical material.

In approaching the problem of selection from the psychological standpoint, it must be remembered that the term psychology does not apply to anything mythical, supernatural, or even out of the ordinary. Psychology today deals with very common aspects of human behavior, and the factors that will be mentioned here are the doings, the feelings, and the characteristics of mankind in general, all of which can be observed in ourselves and in our associates with whom we come in daily contact. That individuals differ markedly in general intelligence, in learning ability, in perceptual and memory faculty, and in emotional balance is a fact well known to us all. Those of us who have had to do with the selection of flying personnel have long been seeking to determine just what psychological make-up is necessary for military aviators. Time permits only a brief discussion of these aspects which are especially important in relation to flying.

Intelligence. When we refer to intelligence, we usually mean the capacity to deal effectively with new situations and to understand new problems by applying the results of past experience. Certainly flying is a novel situation for a human being, and in order that he may adequately meet the many problems involved, it is essential that he possess a satisfactorily high level of general ability. But experience has shown that not all individuals having normal or even superior intelligence make successful military aviators. Intelligence is a complex of many functions and two individuals having the same level of general ability may differ tremendously in the amounts of specific abilities which they possess. Learning to pilot an airplane demands a good capacity for learning, but it is learning of a specialized sort and differs considerably

from the ability to learn Greek or mathematics. At least normal intelligence should be required in all flying students. Those with less than this endowment are slow to understand instructions, do not remember, and have great difficulty in solving their problems quickly and effectively. But we need to know more about the individual's mental make-up than merely his general level of ability.

Learning and Memory. To become a military flyer, one must learn a great many things. Normal rapidity of learning and habit formation are essential if progress is to be satisfactory. As in all other things, individuals vary in their capacity to learn. Some learn quickly and forget right away; others learn slowly but remember for a long time. Undoubtedly, the person who learns quickly and retains well the specific knowledges, skills, and attitudes of the types required for military aviation will inherently be the best qualified.

As a result of learning meaning is given to one's experiences. This understanding and interpretation of stimulation of the senses are known as perception, and simply mean that we understand a situation at a glance because we have learned the meaning of this and that stimulus. Good perception is of the utmost importance to the pilot; in fact, it is absolutely essential. He must use his space-perceiving apparatus almost continuously and to the greatest degree. He sees the ground below, and with experience learns much and perceives many things that are meaningless to one who makes his first airplane trip, such as approximate altitude of the airplane, character of the terrain, direction of the wind, and others.

In flying the time factor is all-important. The speed with which the various maneuvers must be learned and co-ordinated is definitely related to the speed of the aircraft. Many of the responses of the pilot must be learned so well that they become almost automatic in nature, and not just a memorized method of movements of stick, rudder and throttle. Extreme delicacy and discrimination are essential, correct interpretation is demanded, and sound reaction must be initiated with a maximum of speed. When material is poorly learned, or when one's memory errs or falters, one cannot effectively respond, and too often penalties are exacted for failure. It should be apparent then, that normal rapidity of learning and habit formation is necessary in a flyer. This includes a plastic learning faculty to permit quick formation of association pathways, giving correct and successful reactions.

Attention. As we continue considering psychological processes, we note that many of them are closely related, that they often are distinguished from other processes with difficulty, and that they influence each other in various ways. Attention, for instance, has much to do with effective learning, for in order to take instructions well it is necessary to be able to keep concentrated on the subject at hand. Modern airplanes are built for high performance, built with more than one engine, variable pitch or constant speed propellers, retractable landing gears, de-icers, radio and numerous instruments pertaining to engine and flight performance. All these apparatus must be attended to by the pilot, and probably in no occupation is it more important to have just the precise development of attention for that particular job than in piloting an airplane.

The desirable type of individual must have this faculty of attention developed to the proper degree—a too highly developed degree of concentration may even make a dangerous flyer. Such an individual becomes so absorbed in concentration on one particular thing until that goal is reached that he is oblivious to everything else. Individuals prone to "absent-mindedness" are usually concentrating so entirely on something else that they can pay no attention to the problem at hand.

On the other extreme is the distractable individual, who seems to lack the capacity to concentrate at all. His attention is so susceptible that it will not remain fixed long enough for him to comprehend the meaning of any of the stimuli he receives so rapidly. Normal span and control of attention is certainly one of the requirements for a flyer.

Emotion. Perhaps there is no vocation in which the emotional factor plays a more important part than in aviation, for when man is flying he is completely out of his element, surrounded by countless dangerous situations, his life and that of his passengers depending upon an emotional stability which will enable him to react at times with lightning-like rapidity. It is well known that resentment, irritation, anxiety, surprise and many other emotional states retard the thought processes and interfere with normal voluntary control over our co-ordinated movements. While under the influence of an emotion, one may make mistakes and errors of judgment which would not have been made under other circumstances. It is even conceivable that one may become "paralyzed" with fear.

The emotionally unstable pilot is apt to carry financial, family or other troubles into the air with him, with the result that he is preoccupied and inattentive. The question of emotional stability is extremely important and flying personnel should have above the average emotional control.

Reaction Time and Age. The regularity and stability of an individual's reaction time are as important in flying as in any other calling where quick decisions and actions are required. The time factor is so all-important in the flying game that those individuals who are even a little slow in their thinking and actions are at a distinct disadvantage. Reaction time may be modified by many causes, such as infectious diseases, fatigue, and other factors. However, aside from such conditions, individuals vary greatly in their speeds of reacting. The question of reaction time has held a prominent place in studies related to the problem of flying for many years.

Youth is a desirable characteristic of the flyer. Reaction time becomes slower as we grow older, though this slowing down process varies in different persons. With increasing age, particularly in postprime years of life, there is a lessened plasticity of the learning faculty. Habits of long duration guide and fix much of one's activity, and new ways and things are assimilated with difficulty. Age should be given a very definite consideration in selecting those who are to fly.

These then are a few of the psychological phases of aviation which we consider in the selection of the individual who is to fly. We should select only those individuals who have a fortunate combination in desirable degrees of the psychological factors we have here discussed, and such individuals will

not be found to be rare. No doubt many hundreds of thousands of ordinary adults are well equipped as potential military flyers, but it should be remembered that there are others, in not insignificant numbers, who for psychological reasons should definitely not fly.

Maintenance. Maintenance of personnel is not a matter which is peculiar to the Air Force; however, in addition to the usual procedures such as hygiene, sanitation, diet, rest and relaxation, which are essential to all, there are certain specific problems which are unique to aviation.

Therefore, in any logical discussion of the subject it will be necessary to mention only briefly some of the problems that we, associated with aviation medicine, are vitally concerned with as having a direct bearing on the maintenance problem:

1. OXYGEN AND HIGH ALTITUDE FLYING

The composition of the atmosphere is uniform below the stratosphere, i.e., approximately 70,000 feet.

	BY VOLUME
Oxygen	21%
Nitrogen	78%
Rare inert gases	1%

As air is compressible, it is denser at lower than at higher levels so that the decrease in pressure on ascent in 1,000 feet is greater near the ground than it is, for example, at 20,000 feet. At 18,000 feet pressure has fallen to half that of the ground level.

Partial pressure in a mixture of a number of gases is that pressure exerted by any one gas within the mixture. It is proportional to the percentage of that gas in the mixture. Oxygen being approximately one-fifth of the atmosphere by volume exerts a partial pressure of 760/5 mm., which equals 152 mm. at ground level.

Oxygen saturation of the hemoglobin of the blood depends on the partial pressure of the oxygen in the lungs. At ground level the partial pressure of oxygen is sufficient to nearly saturate the blood leaving the lungs, so that taking extra oxygen at ground level for short periods, while doing no harm, does no good except in certain instances. Between 15,000 and 18,000 feet the atmospheric pressure has fallen to 428 mm., and the oxygen partial pressure in the lung to approximately 50 mm. of mercury. When the partial pressure of oxygen reaches 50 mm., the hemoglobin can only be approximately 75 per cent saturated, and the tissues are unable to get sufficient oxygen.

Lack of oxygen affects all tissues of the body, and exposure to even slight degrees of anoxia too slight to produce immediate effects will in time impair efficiency and lead to unnecessary discomfort and fatigue.

a. *The Brain. Psychological.*—Defective judgment, spurious self-confidence; lack of self-criticism; inaccuracy; lack of appreciation of time, and the like.

Reasoning.—Alertness dimmed, all mental processes slowed down, later unconsciousness comes on without the individual being aware of anything abnormal.

b. *Vision. By day* the light may appear dimmed and acuity is dimmed.

By night adequate oxygen is of even greater importance because even the slight degree of oxygen lack at 4,500 feet considerably impairs the ability to adapt one's eyes to dim lights and to discern objects dimly illuminated.

c. *Cold.* Lack of oxygen causes the hands and feet to feel cold, and if this occurs, supplying oxygen brings a flood of warmth within a few minutes. However, extra oxygen will not prevent one's feeling cold if one is inadequately dressed.

It should be noted that the above changes, at least in the earlier stages, are not appreciated by the individual himself. Even syncope is such an imperceptible process, that the subject on recovering consciousness may be completely unaware he ever lost it.

Our Air Force now requires oxygen to be used as follows:

a. All flights of 10,000 feet over one hour's duration.
b. All flights to 15,000 feet regardless of duration.
c. From the ground up when the rate of climb is 2,000 feet per minute.
d. Night from ground up.

2. BENDS OR DECOMPRESSION SICKNESS

When air is breathed into the lungs, oxygen alone is absorbed by the blood cells, but by the simple physical laws all gases pass into solution in the fluid plasma of the blood proportionate to their partial pressure. Thus the nitrogen in the plasma is in equilibrium with nitrogen in the air at ground level. During ascent, the pressure of nitrogen in the air, of course, falls and nitrogen comes out of the blood in just the same way that carbon dioxide comes out of a soda syphon when the pressure is reduced by opening the tap. If ascent is slow, the nitrogen has time to diffuse through the lungs. If, however, the ascent is rapid to great heights, the nitrogen comes out of the blood and forms bubbles in the vessels and tissue fluids, causing the tearing of the tissues and blockage of the vessels. This discovery was first made when investigating the caisson disease, or bends, in divers. Divers at 200 feet are exposed to a pressure of six atmospheres, and, while at this depth more nitrogen is absorbed in their body fluids, as rapid ascent takes place they suffer from bends, but slow decompression will completely prevent the illness. A similar condition may develop when ascent is made to 30,000 feet or more at rates of climb attained with the modern aircraft.

3. ACCELERATION OR ACTION OF CENTRIFUGAL FORCE ON PILOTS

Any aircraft flying along any arc of a circle, whether produced by pulling out of a dive, a tight turn, a diving spiral, or any combination of fighter aerobatics, has acting upon it from the center of the circle a centrifugal acceleration which varies directly as the square of the linear velocity and inversely as the radius of the circle. Weight is a force and is expressed as the product of the mass and the acceleration due to gravity or "G." Hence, when a pilot has acting upon him an acceleration of several times that of gravity, his weight increases in the same proportion: and at a centrifugal acceleration of seven times "G" a pilot weighing 180 pounds normally, weighs 1,260 pounds. Every tissue in the body takes part in this increase in weight. At approximately

seven "G" the blood becomes as heavy as melted iron. Consequently, the weight of the hydrostatic columns of blood, which has to remain unaltered in order to maintain the circulation through the brain on the arterial side and the inflow into the heart on the venous side, increases to an extent that cannot adequately be met with by the venous mechanism which returns the blood to the heart from the abdomen and legs and in the capillaries of the abdominal organs and leg muscles where the cross-sectional area is very large. As a consequence of these circulatory changes, there is a fall in the blood pressure in the large vessels supplying the brain and eyes, and, when this reaches a given value for the individual pilot, failure of vision occurs, which we call the "black-out," and if this force continues for an appreciable length of time, unconsciousness will ensue. It has been constantly noted that a succession of "black-outs" without impairment of consciousness is followed by undue feeling of lethargy, lassitude, impairment of mental concentration, or, in other words, extreme fatigue. Average young pilots in good health will take 4½ to 5 "G" for four seconds without a black-out.

4. OCCUPATIONAL FATIGUE

The word "fatigue" here is used to describe: (a) A complex and rather vague clinical condition which is often thought to constitute a definite disease entity, whenever a subjective sense of tiredness predominates. (b) Intracellular or other tissue changes, resulting from overstimulation.

Occupational fatigue has been a subject of paramount interest to physicians interested in industrial medicine and to medical officers in the military services for a great many years. Its presence greatly diminishes both the quantity and quality of the work rendered by the worker in industry, or the military man in one of the armed forces. At no place in the military service is fatigue so likely to occur, and if it does occur, it is not of such importance as in the Air Force.

The term "fatigue," when used in connection with flying, has come to be attached to a syndrome found in flying personnel, particularly those engaged in operational or combat units. Its manifestations are the effects of such work upon the normal individual being submitted to an abnormal amount of stress. Many terms have been used to describe the condition, such as aeroneurosis, flying stress, operational fatigue, staleness and others. I prefer to use the term "flying fatigue" as it seems to me that this is the most descriptive—any change from the normal can thus be associated with the etiology of the conditions.

Nervous breakdown in pilots has been noted since the early days of flying. In military aviation, where the pilot not only must handle airplanes powered with one or more motors of extremely high horse power and be subjected not only to the effects of the resulting vibration, speed, rapid changes in altitude, but also while managing this machine, to the stress of close formation flying and fighting in the air, fatigue makes its appearance much earlier than when flying for pleasure in commercial airplanes. It must also be kept in mind that the lowered efficiency resulting from fatigue in military flying personnel is very likely not only to affect the individual himself, but also to endanger

indirectly the lives of all those who may be associated with him. Many of our military combat planes of today carry crews of from three to ten men. In carrying out a military operation, exact timing and co-operation on the part of every member of the combat crew are necessary, and the results obtained are not likely to be any better than the efficiency reflected by the weakest member of that crew.

The "Flight Surgeon" of the Army is charged with the *selection* and *maintenance* of flying personnel from the physical standpoint. In the selection of applicants for flying training, he attempts to select only those who not only meet the high physical standards necessary for arduous military field service but also only those who possess the necessary psychological qualifications to enable them to complete flying training and to withstand the flying stress or "occupational stress," which will be imposed upon them to a severe degree by combat flying. If proper selection is made, maintenance of the individual will likely not become a difficult problem; however, our biggest problem in maintenance is flying fatigue. The variability of the relative proportions of the subjective and objective symptoms of flying fatigue renders it difficult to diagnose them in the early stages. The trained flight surgeon will be on the lookout for the early and insidious symptoms of this weakness so as to institute prophylactic measures against its full development, with resulting total loss of the individual to combat flying.

PHYSIOLOGY OF FLYING*

Hazards and Remedies

Lieut. Col. D. Bruce Dill, Dayton, Ohio

FLYING is a hazardous undertaking, and it is fitting to discuss here those hazards that are physiological in nature. It has been popular to think of *anoxia* as the chief hazard of high altitude flying. While it is no longer of paramount importance, it still deserves some attention. The man breathing air at sea level is able to saturate his blood almost completely with oxygen. The range of saturation is remarkably narrow, usually being within the limits of 94 to 96 per cent. This results in a partial pressure of oxygen in arterial blood of about 80 mm. Hg. Man has become accustomed to that condition; the tissues of the body have been organized on the basis of that partial pressure of oxygen in blood coming to them. The one organ most sensitive and which suffers greatest from reduction is the brain. This hazard of oxygen lack arises between 10,000 and 20,000 feet where the pilot is not using his oxygen supply. As he goes higher, using his oxygen supply, even assuming it is functioning perfectly, when he reaches an altitude of about 37,000 feet, he again begins to become

*Lecture XXI, reprinted from *Collected Lectures of the Metropolitan State Hospital*, Waltham, Mass., 1942.

anoxic. The reason is commonly overlooked by medical students and physiologists who do not appreciate the fact as the total pressure decreases a point is reached at which even with pure oxygen the blood is not saturated. This critical altitude is around 37,000 feet, and breathing oxygen at 40,000 feet is roughly equivalent to breathing air at 10,000 feet. The limit of consciousness breathing pure oxygen is near 45,000 feet.

Another hazard and one much less well understood is *aeroembolism*. It depends not upon oxygen supply but upon the absolute pressure. At 18,000 feet the pressure on the body is just half an atmosphere, and at 40,000 feet it is one-fifth of an atmosphere. As a result, nitrogen tends to be released from solution in body fluids. As we sit quietly at sea level we have in our lungs a partial pressure of nitrogen of something over 550 mm. That gas in the lungs must necessarily be in equilibrium with the blood passing through the lungs, and the solubility of nitrogen in the blood is such that about 1.4 volumes per cent of gaseous nitrogen is dissolved in it. Every liter of the blood will contain about 14 c.c., and that is also true of the water in the rest of the body. A larger proportion dissolves in body fat. The analogy has been drawn between the state of this gaseous nitrogen in the body fluids and the state of carbon dioxide in a bottle of soda water. In either case, when the pressure is suddenly decreased, gas bubbles form.

There are a number of curious facts about aeroembolism that we do not understand. We know that at 18,000 feet the pressure on the body is reduced one-half, and yet no one ever experiences any trouble from aeroembolism here, nor even at 25,000 feet. At 30,000 feet very few people will experience symptoms during the first hour of exposure. At 35,000 feet no one is likely to suffer during the first few minutes.

The best guess as to the explanation of these facts is that while the nitrogen escapes from solution at once, the first bubbles formed are too small to cause trouble. In time they increase in size by coalescing with adjoining bubbles by the diffusion into them of carbon dioxide and water vapor oxygen.

A third hazard is that of *acceleration*. We know that a man may faint on a hot day while standing at attention, i.e., when exposed to 1 "G." When we consider that a man in an aircraft is not uncommonly exposed to three times that force and for short times to five or six times that acceleration of gravity, we can readily imagine that fainting is very likely to occur. In a pull-out from a dive, the "G" is often as great as 5 for a period of a few seconds. If the man is sitting erect, venous return from below the heart will be stopped, and the arterial supply above the heart, and in particular to the brain, will be handicapped. Within a short time the heart is inadequately filled. There will be but a small amount of blood discharged with each beat, and the tendency will be for blood that does leave the heart to go down rather than up. Most of our knowledge of the physiology of acceleration has come from Germany, where a centrifuge has been in use for some years. There are many important questions awaiting solution, such as the possibility of selecting men who are resistant to acceleration, of determining the factors that make him either more or less resistant to acceleration, and of training men in the techniques of resisting acceleration.

A fourth hazard of flying is *cold*. This needs no special emphasis here, because the hazard of cold in high altitude flying is little different from that experienced by the man on the ground in cold climates. One point requires special mention—the relation of shivering to the problem of oxygen supply. In the present oxygen-supply systems it is assumed that the man is not going to use very much oxygen. However, if the man gets very cold and starts shivering, his oxygen consumption then may go up to two to five times, and then two hazards may be superimposed, anoxia developing if his oxygen system is inadequate for this emergency.

Vibration can be put down as a fifth hazard. This properly includes noise. Some individuals are extremely resistant to noises. Others are rather sensitive, and it is safe to assume that the exhaustion experienced in flights of many hours' duration depends in no small degree on this hazard. In a project at Harvard designed to study physiological effects of noise, physicists have been able to reproduce the characteristics of the noise of an airplane propeller with extraordinary fidelity.

A sixth hazard which cannot be separated from these others is *fear or anxiety*. It arises from being in a strange environment, from being uncertain whether he is going to reach his field or whether, when he gets back, he will be able to land. If we add to the hazards already mentioned the emotional experience of combat, it is quite clear that the combined effect is a serious strain on the organism, a strain that can be tolerated once or twice or a few times but cannot be tolerated too often; there must be opportunities for recuperation.

Having presented some of the facts about the hazards of high altitude flight, I am going to return now to a more detailed discussion of some of them, beginning with anoxia. There is, first of all, an adaptive response to anoxia that is believed to depend on stimuli arising in the carotid body. Respiratory volume is increased, thus preventing such a reduction in arterial oxygen as would otherwise occur. The extent to which respiratory volume can increase in extreme anoxia has been demonstrated by Dr. Corwin and Mr. Horvath here at the Metropolitan State Hospital last summer. The respiratory volume reached 25 to 30 liters per minute merely from the stimulus of oxygen lack. The same patients, if poisoned with carbon monoxide, would become unconscious without any increase of respiratory volume.

What are the effects of oxygen lack on the muscular system? We know that a single contraction of a muscle can be carried on equally well whether oxygen is present or not. It can be shown that a man at an altitude of 20,000 feet has as great strength as under ordinary conditions. However, if he attempts to continue, there will be a breakdown, because recovery processes are handicapped by oxygen lack.

In the nervous system the story is different. The functioning of the nervous system depends upon a virtually continuous supply of oxygen and almost immediately, when a given stage of anoxia is established, the various mental functions show decreased efficiency. Sleepiness, for example, is one of the common effects of anoxia. A man exposed to moderate anoxia may sleep for hours at a time. With prolonged and more severe exposure, the sleepiness may verge on unconsciousness. Stupor is not uncommon. The phenomenon of persevera-

tion is commonly seen. We have sometimes asked anoxia subjects to write a sentence that includes the phrase "around the rugged rock." It is a common error, when they get to this expression "around the rugged rock," a phrase which in itself suggests repetition, to write repeatedly "around the rugged rock."

If anoxia is prolonged, more unpleasant effects, such as nausea, headache, and vomiting, may occur. The headache may become most severe after the period of exposure, as is also true in carbon monoxide poisoning.

An instructive illustration of both the direct and indirect effects of failure of oxygen supply may be given. The test subject was riding a bicycle in the chamber at 40,000 feet. We had him hooked up to a cardiotachometer, and I was getting ready to make an arterial puncture on the man while riding the bicycle in order to determine the adequacy of his oxygen equipment. I picked up the needle and syringe and started to put a sponge in a dish of alcohol. This dish instead of having the usual dye-colored fluid had a clear solution. I wasn't sure it was alcohol and I took off my oxygen mask momentarily to sniff it. A few seconds later I again took off my mask to announce over the teletalk that I was going to make the puncture. Then I walked around, facing the subject, but as I got into position with the syringe in one hand and the sponge in the other, I slowly settled to the floor and leaned my head back against the wall of the chamber. This, for the first few seconds, did not seriously alarm the man on the bicycle. He thought it was a peculiar thing to do, but in about ten seconds he fully appreciated that I had passed out, and also that there wasn't anything he could do about it. He was hooked up to an oxygen system that didn't permit him to get within reach of me. There was an observer on the other side, who signaled to the chamber operator outside, and within two minutes we were down to ground level. The most interesting observation made in that case was on the man riding the bicycle. His pulse rate was 110 before my collapse; it rose to 120 when he first saw me acting curiously, and then it went to 185 during the next ten seconds, when he appreciated that I had passed out. The lesson from this is that in a plane where you are at a higher emotional pitch than is likely to be reached in a chamber, an accident to one man is certain to have a very powerful effect on some of the other men. That is the time when serious mistakes are likely to be made, leading possibly to disaster.

Such an incident illustrates the sort of experiences that one faces in the air, and I want to emphasize once more that in studying the problems of high-altitude flight, you should divorce from your mind the deep-seated idea that they can all be answered by putting mice in a cage and subjecting them to low oxygen.

Returning now to the subject of aeroembolism, I wish to say a little about protection against it. Since it is produced by the formation and growth of nitrogen bubbles, it would appear reasonable to try eliminating some of this nitrogen before starting a flight. The most effective means consists in breathing pure oxygen during exercise, the nitrogen, of course, being gradually evolved by the lungs. Exercise that raises the metabolism to four times the

resting level, involving a respiratory volume of twenty liters a minute and an increased circulation rate, will result in the release of at least half the nitrogen of the body within a half hour. The man is then able to undergo a greater reduction in pressure or to stand a very much longer exposure to a given altitude than would ordinarily be the case. This procedure is likely to have usefulness in some missions. It obviously cannot be used in defense warfare, because a man on defense has to be ready on a minute's notice. It seems that it could be made practical in offensive operations or whenever missions are planned ahead of time.

The obvious method of protecting against the anoxia and cold, as well as the aeroembolism of extreme heights, is the pressure cabin. You have heard of the commercial plane that maintains a small positive pressure in the cabin so that when it is 20,000 feet, the effective pressure inside is equivalent to 10,000 or 12,000 feet. There is considerable advantage in this. The military pressure cabinet is still on the blueprint stage so far as I know. On paper at least, it is possible to make a cabin that at 40,000 feet will maintain a pressure within equivalent to 10,000 or 12,000 feet. Compression of that air will heat it enough to keep it comfortable.

Something should be said about *visual function* of pilots. A subject about which I presume you have heard much within recent years is night blindness. There was a great furor about two years ago, and one of the first published papers in this field indicated that vitamin A deficiency was rather common. Many measurements have been made during the last year in military personnel, and practically speaking, you never find a case of poor night vision improved by vitamin administration. However, these studies have been useful in revealing a wide variation among healthy men, a variation that appears to be inherited; at any rate, it is relatively constant in a given man. It remains to determine the practicability of selecting men with exceptional night vision for night flying.

SOME PROBLEMS IN AVIATION MEDICINE*

Ashton Graybiel, M.D., Boston, Mass.

Aviation medicine is a newcomer among the medical specialties. It was born during the First World War, when the lack of fitness among airplane pilots became strikingly apparent. Some idea of the urgency of the problem at that time can be gained from the fact that in the British forces 90 per cent of the plane casualties during the first part of the war were due to pilot error, and only about 2 per cent of the plane casualties were due to enemy action.

Steps were immediately taken to improve upon the method of selection of pilots and to do a better job in the maintenance of their health and fitness. Certain criteria were laid down which served as a yardstick for selection. For the most part, they dealt with the physical criteria for selection, and the value of the standards laid down at that time is attested by the fact that they have not been materially altered since.

Following the First World War, aviation medicine received a setback, and interest was not revived until the great development of commercial aviation, which began in the late twenties. At that time various studies were made, not only with regard to the care and selection of pilots, but also with regard to the comfort and safety of passengers. Now the major interest has again shifted back to military aviation, with the onset of the Second World War. At the present time, there are many and important problems requiring solution, and this condition has come about so abruptly that there is a great lack of trained personnel in this field.

Many people at this time are under the impression that the modern airplane has reached such a state of perfection that the pilot's work has, therefore, become much easier and simplified. Actually almost the reverse of this is true. The airplane, as Dr. Hunsaker of the Massachusetts Institute of Technology points out, is still subject to the laws of gravity, will still slip and fall into a spin, and still presents many of the "old difficulties" in flight. With every increase in the reliability of the airplane, there has also been an increase in expectancy of performance. Increasing the speed of the plane and the height to which it may ascend has served to introduce such problems as aeroembolism, anoxia, and the black-out. None of these problems were of any great significance during the First World War, but are of first importance at this time.

THE SELECTION OF PILOTS

Someone has said that out of about thirty-odd billion people born in the world, only about five thousand ever amounted to much, and that is somewhat the way it is with the selection of pilots. Out of a large number of apparently

*Lecture XXII, reprinted from *Collected Lectures* of the Metropolitan State Hospital, Waltham, Mass., 1942.

healthy individuals, only a small number are really fitted, both physically and psychologically, to pilot an airplane. Armstrong has stated that if a man is examined and is found to have no obvious physical defects and is satisfactory for any ordinary type of occupation, he still could have a hundred defects which might disqualify him from becoming a good pilot. In addition to the physical defects there are, of course, the psychological aspects to be considered, and the pilot's aptitude for flying.

Some idea of how few are fully qualified for military pilots is gained from a study of the pilot selection at one of the training stations. The majority are selected from the students in nearby universities, although a number apply from all over the United States. First of all, these college students are sent a questionnaire, which they fill out; if certain basic educational and physical requirements are met with, they are given the physical examination. This examination is quite thorough. It not only includes the usual physical examination but also includes a careful examination of the special senses and a "short-arm" psychological examination. As a result of this procedure in a typical sample of 753 candidates, only 42 per cent were accepted as representing sufficiently good material to start training. Thus, in an already select group of individuals, about 60 per cent were immediately disqualified. Of those that are finally selected as student pilots, somewhere between 25 per cent and 40 per cent are eliminated during the first six months of training. This represents, of course, not only a large economic loss, but, what is more important in wartime, a serious loss of time and effort.

A chief problem then is to devise some system of selection whereby only those who are likely to succeed will be permitted to enter training. The problem has been attacked in various ways. For example, the physiological and psychological characteristics of successful pilots have been analyzed in an effort to obtain criteria for selection. Another method has been to carry out various examination procedures and tests on all the incoming pilots and then see if those failing and those succeeding make different scores on the various tests. It is not to be hoped that any single test will separate the good from the bad material, but it is hoped that some day a battery of tests will be discovered which will greatly aid at least in the selection process.

Much time and care are now given to the maintenance of health and physical fitness in pilots. Periodic examinations now are required in order to insure that certain physical requirements are being met. In commercial aviation a limit of eighty-five hours a month has been set as the maximum flying allowed. Gradually, there has come about an increasingly close relationship between the pilot and the flight surgeon, with the common objective of keeping the pilot flying as long as possible.

OXYGEN LACK

One of the most important problems in aviation medicine results from the progressive decrease in oxygen pressure with increasing elevation. Every physiological function depends upon the supply of oxygen. and when this is reduced, the function must be restricted accordingly. The extent to which the body is affected depends not only on the altitude reached but also on

the rate of ascent and the length of time aloft. Certain physiological characteristics of the individual are important as is the state of health. As Dr. Dill has pointed out, the aviator or airplane passenger makes certain adjustments as the result of reaching a high altitude, but, unlike the mountaineer, he undergoes little or no acclimatization even though oft-repeated flights are made.

Commercial airplanes for the most part fly at altitudes below 10,000 feet but in certain regions they fly at altitudes of 14,000 to 15,000 feet and may on occasion go even higher. A recent Civil Air Regulation requires the crew to use additional oxygen if flying above 12,000 feet or if flying above 10,000 feet for thirty minutes or longer. Nearly all the commercial planes which fly at altitudes over 10,000 feet contain equipment for oxygen administration to passengers. In military aviation most of the flying is still done at relatively low altitudes, but some is done at elevations between 35,000 and 40,000 feet. At 40,000 feet the alveolar oxygen tension of a pilot inhaling pure oxygen corresponds to that of a pilot breathing air at 11,000 feet. From a practical standpoint it is nearly impossible to prevent slight leakage when using an oxygen mask, so that the degree of anoxemia usually exceeds the theoretically calculated amount.

Very briefly I will discuss some of the effects of oxygen lack, particularly on the nervous and circulatory systems.

If anoxia is rapidly produced, as in an actual or simulated ascent in an airplane, the first and most important effects are seen in relation to the central nervous system. Psychological impairment to a slight degree may be observed below 10,000 feet but it becomes more definite at higher elevations. At first there may be a feeling of well-being and even euphoria. A false sense of enhanced powers is often experienced, which is in many respects similar to mild alcoholic intoxication. This state gradually passes into one of mental dullness at elevations around 14,000 to 15,000 feet. and some persons become sleepy. At this stage of decreased sensory acuity vague feelings of uneasiness and bodily discomforts tend to disappear, the anoxia acting somewhat as an analgesic. At higher elevations the signs and symptoms of anoxia become progressively more marked, and fainting or unconsciousness occurs. Few, if any, unacclimatized persons remain conscious at elevations in the neighborhood of 25,000 feet.

The obvious treatment for symptoms of anoxia, or better yet, their prevention, rests in supplying an additional amount of oxygen. The most practical method of giving additional oxygen is by means of a mask fitted over the nose and mouth. This procedure is quite satisfactory for elevations up to 35,000 feet or a little higher, but above that level the partial pressures of water vapor and carbon dioxide in the alveoli form too large a part of the total pressure and even breathing 100 per cent oxygen is insufficient. It then becomes necessary to supply oxygen under pressure as in a supercharged cabin plane.

My own interest in aviation medicine is concerned chiefly with problems relating to the cardiovascular system. In considering this problem, it is essential to distinguish between the direct effects of oxygen lack on the heart and the effects on the peripheral circulation both in the healthy person and in the patient with heart disease.

With regard to the heart itself there is much evidence that a person with a normal or even a diseased heart may withstand surprisingly severe degrees of oxygen lack without evidencing heart failure.

Healthy subjects during high altitude flight or those exposed to low oxygen tensions in the laboratory rarely complain of symptoms directly referable to the heart.

The dyspnea which may be noticed is not severe and is due to stimulation of the peripheral chemoreceptors by anoxemia and is not a sign of heart failure. Pain of cardiac origin is never noticed and palpitation very rarely. The fatigue which commonly appears during long flights, and the state of easy fatigability which follows, is probably related to the effect of anoxia on the central nervous system.

Of all the circulatory changes due to diminished oxygen tension, acceleration of the heart rate has been studied the most. With successive decreases in oxygen tension the rate continues to increase slowly, but the increase in rate is not marked until extreme degrees of anoxemia are reached. Sometimes there is little change in the heart rate or actual slowing and bradycardia may be associated with the collapse.

The changes in blood pressure due to increasing anoxia follow several fairly well-recognized patterns. In the majority of healthy persons there is little change until the oxygen in the inspired air has fallen to low levels. Then there may occur a gradual rise in systolic and a fall in diastolic pressure, with consequent increase in pulse pressure. In susceptible persons exposed to moderate degrees of oxygen deficiency, fainting may occur and there is a sudden fall in both systolic and diastolic pressure. This fainting reaction is in the nature of peripheral vascular collapse and is caused by cerebral anoxemia and is not due to heart failure. In a few subjects there is little change in blood pressure until unconsciousness supervenes. It is only at this stage of crisis that the fall in blood pressure may be directly attributable to a failing heart.

The cardiac output increases in healthy persons at rest under conditions of moderate anoxia. This increase may be regarded as a compensatory or adjustment mechanism. With marked decreases in oxygen tension the cardiac output may fall as a direct result of cardiac anoxia, but this stage is never reached under present flight conditions. More studies along this line are necessary before the relationship between anoxia and cardiac output is properly understood.

There are many reports, especially in the older medical literature, describing cardiac dilatation or hypertrophy in mountaineers or in those resident at high altitudes. There are also a few published observations purporting to show that cardiac enlargement may occur in aviators or in subjects exposed to reduced barometric pressures. Etienne and Lamy observed slight to moderate cardiac hypertrophy in ten of the eleven aviators of a celebrated escadrille. They considered that this hypertrophy developed in two stages and invariably involved the left ventricle. In the first stage, which lasts only a few months, the heart increases in size relatively rapidly, and this is followed by a second stage lasting two to three years, in which the hypertrophy is slowly progressive.

Whitney observed dilatation (by percussion) of the heart in five of ten healthy subjects as a result of a reduction of barometric pressure simulating an altitude of between 14,000 and 20,000 feet. Increases in transverse diameter of from 3 to 5 cm. were said to occur. Le Wald and Turrell, on the other hand, in a carefully controlled roentgenological study of 89 aviators under conditions simulating high altitude, observed a decrease in size of the heart in 14, no enlargement in 66, and an apparent enlargement in 9. In 6 of these 9 the increase in size was explained by alterations in the position of the diaphragm while in the remaining 3 the transverse enlargement was only 0.4 cm. or less. It is now quite generally agreed that the normal heart, if the subject is at rest, does not dilate even with greatly lowered oxygen tensions. This conclusion is borne out by animal studies in which it is shown that cardiac dilatation does not begin until the oxygen saturation has fallen to about 50 per cent or below.

The electrocardiographic changes have been studied during actual flight conditions as well as under conditions simulating high altitudes in the laboratory. In healthy persons these changes consist of progressive lowering of the S-T segments and T waves with increasing anoxia. Occasionally, the T waves may be diphasic or even slightly inverted. Some of the most marked electrocardiographic changes observed in healthy subjects were obtained by Dr. Corwin and Mr. Horvath in experiments on acute anoxia conducted in this hospital. Especially marked was the lowering of the S-T segments and T waves.

That alteration in the carbon dioxide tension alone may cause electrocardiographic changes has been described by Barker and others, and we have confirmed these observations as to the lowering of the T waves and slight downward displacement of the S-T segments following overventilation for three minutes. That overventilation may be a factor in producing the electrocardiographic changes observed at high altitudes is highly probable.

Thus, in normal persons the symptoms which may appear under conditions of civil or military aviation and the changes in circulatory dynamics do not indicate heart failure but may be considered in the nature of adjustments or compensatory reactions to the oxygen deficiency; the most trustworthy evidence we have supports the view that the normal heart is not damaged. With respect to peripheral circulatory collapse this may occur in susceptible individuals even at relatively low altitudes and is due primarily to the effect of lack of oxygen on the central nervous system.

DECOMPRESSION ILLNESS

Decompression illness is another hazard which must be considered. When the atmospheric pressure is suddenly decreased, such as occurs during rapid ascents to high altitudes, symptoms arise as a result of the formation of gas bubbles in the body tissue and fluids. This bubble formation takes place in accordance with the laws governing the solubility of gases. Blood passing through the lungs is exposed to the gases in the atmosphere, and each gas is absorbed according to its partial pressure. Relatively large amounts of nitrogen go into solution because of its high partial pressure, while oxygen and carbon dioxide are taken off in smaller amounts. The body has special transport systems for oxygen and carbon dioxide but not for nitrogen, which is relatively inert and obeys the laws of simple solution. Now, if the atmospheric pressure

is decreased, the body tissues and fluids tend to give up the dissolved gases, principally nitrogen, by way of the lungs. If the decrease is sudden and of the order of half an atmosphere or more so that the concentration of nitrogen is at least double what it should be, this gas will come out of solution and form bubbles to which is added some oxygen, carbon dioxide, and water vapor from the surrounding blood and tissues. There is considerable difference in opinion regarding the height of ascent before clinical symptoms appear. Armstrong states that gas bubbles are found in the spinal fluid at 18,000 feet while bubbles in the blood and tissues generally have not been found below 30,000 feet. He believes symptoms are rarely noted below 30,000 to 35.000 feet. However. English observers are of the opinion that symptoms may appear at lower altitudes than these. The most dangerous symptoms occur, of course, when bubbles appear in the blood stream. Aeroembolism of a cerebral artery may lead to severe central nervous system disturbance while if the coronary arteries are involved, heart failure may result. This, then, becomes an important problem, especially in military aviation. Dr. Dill, in the previous lecture, has told you of his striking experiences with aeroembolism.

ACCELERATION

Another adverse influence on the cardiovascular system is that of centrifugal forces (due to positive accelerations amounting to as much as nine times the force of gravity) which may be encountered during the combat maneuvers of modern fighter aircraft. The effects of positive accelerations when these are in the longitudinal axis of the body are observed most dramatically in the displacement of blood from the upper to the lower portions of the body. Forces greater than 4 to 5 "G" acting for three seconds cannot be sustained without symptoms. If the force acts only for a short time, the blood supply to the eyes and then the brain becomes deficient, and the vision becomes dimmed or lost. If the centrifugal forces act sufficiently long, the venous return to the heart becomes inadequate and complete circulatory collapse ensues. Dr. Dill, in the previous lecture, has described the underlying physiological changes and the symptoms produced.

AIRPLANE SICKNESS

Sickness in an airplane is usually due to the movements of the plane or oxygen lack, or a combination of both. Sometimes the former is referred to as airsickness and the latter as altitude sickness, but as both conditions may be present at the same time, a term such as plane-sickness is useful.

Airsickness is akin to seasickness both in etiology and symptomatology. The up and down movements of the plane are the chief immediate cause, but many other factors such as fear, fatigue, alcoholism, etc., play an important role. Persons who develop airsickness readily do not make successful pilots, but on occasion even a pilot of long experience becomes sick.

Nausea and vomiting may be caused by oxygen lack and may be a distressing part of acute altitude sickness. Pilots will often fly higher than usual in order to find less turbulent air. Often a compromise must be worked out between "rough" air and adequate oxygen and "smooth" air and deficient

oxygen. The story is told of a South American pilot who was informed by the steward that only eight box lunches had been put aboard for fourteen passengers. He said, "Don't worry, I will get you out of that fix," and began to ascend to a higher altitude. In a short time so many of the passengers had lost all notion of eating that there was a surplus of box lunches.

EARACHE

Changes in atmospheric pressure naturally affect any gas-filled cavity which is closed. Of chief importance in this regard is the middle ear. Normally, the Eustachian canal is only a potential tube, and it may be necessary to chew gum, yawn, and manipulate the tissues anterior to the head of the mandible in order to open the tube temporarily. If there is swelling due to a cold, the individual may suffer acutely, and sometimes it has been necessary to delay a landing because of this.

CONCLUSION

In conclusion it may be emphasized that many problems pertaining to aviation medicine await solution. Only a few have been mentioned here and notable omissions include pilot fatigue, cold, glare, vibration, etc., and the many problems of medical organization.

PHYSIOLOGY OF FATIGUE*

Factors and Criteria of Endurance

Lieut. Col. D. Bruce Dill, Dayton, Ohio

THE subject that I am going to discuss first is the dependence of fatigue on stresses. It is well-known to all of you in your experience as medical students that fatigue is a phenomenon that can be studied in an isolated muscle. The muscle can be given a task to do which at first it is able to do, and for some time, minutes or longer, it will continue to do at a rate which is maintained constant. Eventually a time will come when the work out of that isolated muscle will begin to fall off. That very simple conception of fatigue is applicable in some respects to all forms of fatigue, whether it is physical or mental. We say that fatigue is a state in which the organism has lost its capacity to carry on. It has a limited capacity for work. In the isolated muscle we can tell pretty well what some of these changes are. If the work has been carried on, for example, in an atmosphere of nitrogen, chemical changes can be detected by analysis which depend on the use of the energy reserves of that particular system anaerobically. If the system has been in an atmosphere of oxygen, work will be carried on longer, and the nature of

*Lecture XIX, reprinted from *Collected Lectures* of the Metropolitan State Hospital, Waltham, Mass., 1942.

the breakdown will be different. In the intact organism the picture is more complicated, but we can produce a state in the sprinter, for example, similar to the state seen in the isolated muscle. The sprinter is called upon to transform an enormous quantity of energy within a very short time. He has supplied nearly all of the energy from certain reserves that can be used without oxygen. When the work is done, there is a period of recovery in which extra oxygen is used, and eventually the original state of the organism is restored.

Another type of breakdown is one in which there is less heavy stress, but one of much longer duration. To give an illustration we enter another field of sport, that of the marathon race. In this we see a man working at high capacity for two and one-half or three hours. The chemical picture in this case is a very different one. The quantity of anaerobic energy available to a marathon runner is not of any significance. Since his energy expenditure is distributed over a period of two and one-half or three hours, he must rely upon oxidative processes. If we draw blood from a marathon runner when he has finished the race and compare its composition with that drawn from the man who has finished a sprint, we get important clues to the processes which have gone on within the muscle in the two cases. In the sprint we may find a blood sugar concentration of 150 or 200 mg. per cent. We may find a lactic acid concentration of 150 mg. per cent, which is to say fifteen times the normal resting level. The high blood sugar concentration in the sprinter may be interpreted as meaning that he has a copious supply of available carbohydrate. Because of the physical exertion plus the emotional factors involved, his reserve of carbohydrate has been mobilized and made available for this strenuous exertion.

In the marathon runner at the end of his race we may find blood sugar concentrations in occasional instances as low as 50 or 60 mg. per cent and lactic acid concentrations of 15 or 20 mg. per cent. However much the emotional situation may have raised the blood sugar in the beginning, by the time the race is over the carbohydrate reserves are depleted, blood sugar is apt to be at a low level, and the fuel is almost exclusively fat. The fact that his lactic acid concentration is low is evidence that he has not been expending energy anaerobically; oxygen has been supplied as fast as the fuels require it. These two contrasting conditions, the one depending largely upon anaerobic work, the other depending exclusively on aerobic work, represent two types of stresses placed upon the organism. The first is a very intense stress of short duration; the second, a less intense stress of longer duration.

The third type of stress to which attention must be paid is that of moderate degrees of exertion carried on for a very much longer time. We can give as an illustration of that the present-day laborer in heavy industries, for example, who still has hard work to do and who today may be working overtime—ten hours a day instead of seven. His fatigue is more like that of the marathon runner than it is like that of the sprinter; however, the biochemist cannot tell us very much about the fatigue of this laborer who may work ten or twelve hours a day. We know this man experiences fatigue, but it is composite in nature, made up in part of physical factors and in part of psychological, or if you wish, mental factors.

In that connection, I think it is worth while to refer here to the experience in England during the last year with overtime labor. This subject was studied very thoroughly in England during the last war, and the conclusion was reached that beyond some reasonable limit, nothing was gained by lengthening the work week. However, history repeats itself, and a year ago at the time of the collapse of the French, the British workman was called upon to give up his holiday weekend, to give up his leave, and to put in extra hours, mounting up to seventy or eighty hours a week. For a few weeks the output increased, and then it began falling off, and before long the weekly output had decreased. An inquiry was made by officials appointed to consider this particular question. They reached a number of significant conclusions; one of the most important is that under their conditions the most effective work week did not exceed fifty-five or fifty-six hours. They analyzed many individual instances of failure to maintain weekly output. After men had been tired out by these long hours, they decided they must have a day off. Instead of Sunday, when they received extra pay, they would take Wednesday. Among those who tried to put in these long work weeks there were more illnesses, increased loss of time because of accidents, and a general breakdown of morale. After this survey had been made, it was recommended that the work week should not exceed fifty-five or fifty-six hours. This experience has a practical lesson for America, because increasing pressure is being put on workmen for greater output. They are being encouraged to give up their vacations, and I understand that many workmen in this country are, at present, putting in seventy or eighty hours a week. This is a very shortsighted policy bound to fail of its purpose in the long run.

Another type of stress involves very little in the way of physical effort but does involve mental or emotional stress of various sorts. I am not qualified to discuss this here; it is a field in which you are experts and I am not, but I again want to give you a simple illustration, and perhaps at the end some of you will wish to make some comment on it. It is not only workmen who are called on to put in overtime; executives are doing so habitually. I think this is a mistake, whether in private business, among civil servants, or in military circles. The idea that a man can work at his desk for eight hours a day, go home and work another four hours at night is fundamentally unsound. It produces a fatigue that results in decreased output. Such an executive is likely to find himself going through the motions without thought or considerate action. I am going to risk saying that a good many of our difficulties today arise from the fact that the men at the top are too busy to think.

The second question which I wish to discuss is the dependence of fatigue on endurance. No matter what training is given a group of candidates for a track team, some will turn out to be superior and some inferior. In other words, one aspect of the dependence of fatigue on endurance is the native endowment. Whether we speak of the purely physical endowment or of mental characteristics, there are inherent differences which must be taken into account. Differences in native endowment are important in the selection of pilots as those of you who are medical officers well know. The same is true for selection of men in any walk of life. Our sprinter is a man with a very unusual

endowment; unusual mental powers are not required, but he does have legs of a particular type, a heart of unusual capacity, and a will to "put out." In prolonged physical effort a different type of endowment is required. The sprinter is likely to be a short man with heavy legs, whereas the successful marathon runner is commonly thin and wiry. We have made some tests of the capacity of various types of athletes in the Fatigue Laboratory. The one striking characteristic of the highly successful distance runner is his very great capacity for supplying oxygen to his body. The most notable example is Don Lash, the two-mile record holder of a few years back. He weighs 140 pounds or something of that sort. In a laboratory test we found that he could supply 5.35 liters of oxygen per minute. Most of us here cannot supply much more than one-half that much. That characteristic depends first on the capacity of the lungs to absorb the oxygen, of the heart to circulate the necessarily large quantity of blood required, and finally, a distribution of capillaries in tissues that favors the rapid delivery of as much oxygen to the cells that are doing the work.

The executive who can do this job of working twelve hours a day without breaking down must have very unusual mental endowment. He is a man who is able to take these continued stresses and bear up under them. He is able to consider one question at a time, settle it, drop it from his mind, and take up another. I say again that I am not qualified to discuss fatigue of this sort, but it intrigues me a great deal.

The other point important to this subject, i.e., to the dependence of fatigue on endurance, is, of course, the role of training. I said that any group of candidates for a track team could be trained indefinitely and great differences in performances would persist. However, all of these men are going to improve, and it is a very interesting physiological problem to determine the nature of this improvement. Why is it that a man can report for track team at the beginning of the year able to run a mile in five and one-half minutes and after three months' training become able to run one mile in four and three-fourths minutes? That improvement in the course of three months is not impossible. We have made a good deal of study of that development and know a good deal now as to just what happens in such an individual. In the first place, the improvement is, to a considerable extent, dependent upon skill or coordination. The man at the beginning is not merely covering a linear distance of one mile, but at every stride he is raising his body much more than is necessary. With every lift of his body a certain amount of energy must be expended. If you study moving picture records of the skilled runner as compared with the unskilled runner, you will see that the skilled runner goes along with only a slight undulation of his body; a large portion of his energy expenditure pushes his body forward.

There is also the development of conditioned reflexes. The coach at the beginning emphasizes time after time the proper methods of running. At first the runner takes thought for every stride, but eventually after he has done this for weeks or months he is able to run without giving thought to these aspects of his job, and then he has time available to consider the other aspects of running, to pay some attention to his competitors, and to judge the timing of his race.

That simple illustration applies to every walk of life. We have seen, for example, steel mill workers carrying out operations with ease that are simply impossible of attainment by the inexperienced man. That is possible because they have learned to do the job the easy way; they have acquired conditioned reflexes such that without giving thought to their job they can carry it through. That has great advantages in industrial jobs other than the mere conservation of physical energy. It means that the man who has learned his job well enough to carry it through without much thought has his mind free for reveries.

No doubt part of the role of physical training is the increase of muscle mass. The blacksmith has the large and powerful arm; it has become so in part because of the training it has had. No doubt muscles increase in size and strength with continued use; they hypertrophy if you wish to use that word. We have heard of the hypertrophy of the heart due to hard muscular effort over a long period of time. As far as I know, cardiologists have found nothing necessarily abnormal about large hearts in athletes.

In a man undergoing strenuous training there may be an increase in capacity for utilizing energy aerobically. A man before he has become trained may utilize three liters of oxygen a minute, and maybe 3.5 liters a minute after strenuous training. With prolonged and very strenuous training, it can be increased more than that. There may also be, as reported by Robinson and Harmon of the University of Indiana, an increased capacity for anaerobic utilization of energy. The highly trained man can push his blood lactate to twice as high a level as is attained by the untrained individual. That is an indication the anaerobic utilization of energy can be developed by long strenuous training.

The third topic I wish to discuss is the question of tests of physical fitness and the criteria of physical fitness. Unfortunately, there isn't any adequate, simple test of physical fitness. As physicians you all employ some simple test of physical fitness. You have your patients walk up and down stairs or step up on a chair or something of that sort, and you get some sort of idea as to their physical fitness. Some of you are familiar with Schneider's test. While useful for some purposes, this apparently doesn't give a reliable index to physical fitness. It is still used by flight surgeons, and it is believed to be useful in judging neurocirculatory stability. A reliable measure of physical fitness must put the whole body under a stress, calling for maximum effort, not merely by a small group of skeletal muscles but by the heart itself. Enough skeletal muscles must be put in use to approach the capacity of your cardiovascular system.

In one such test developed at the Fatigue Laboratory, the man first walks on a motor-driven treadmill at about 3½ miles an hour and on a 9 per cent grade. This is continued for about ten minutes, while we collect expired air, determine his oxygen consumption, measure his heart rate, make various blood tests, etc. This serves as a warming up period for the later test. After a few minutes' rest we speed up the treadmill to 7 miles per hour and have him run for five minutes or for a shorter time if that is impossible. In this test a measure of capacity of the individual to supply oxygen to his tissues is obtained;

this, to our minds, gives the most precise index of the over-all fitness of the cardiovascular system, and for that matter of the whole body as a machine. That figure, the maximum intake of oxygen, shows a wide variation among individuals, depending upon the original physical endowment, the training which a man has had, and the age of the individual. He reaches his maximum around the age of 20 to 25, and thereafter declines, perhaps as much as 50 per cent by the time he is 70. This sort of test is like that the engineer makes if he is called upon to compare the performance of two engines. He doesn't merely measure energy output and gas consumption while the engines are idling.

Some such test, if simplified, may have practical applications. We know that the Germans segregate unusually qualified individuals; very extensive psychological and neurological tests are made of men to find men of unusual mental capacities, and we know that they have troops sorted out on the basis of physical endowments. Storm troops were organized in the last war, and they are certainly playing a role in the present war. How can you select such men? That is a subject to which much thought has been given at the Fatigue Laboratory, Harvard University, during recent months. The "Pack Test," developed there and widely applied in both civilian and military circles, appears to give the most reliable index to physical fitness. Men who pass this test successfully not only are good athletes, they are tough fighters.

THE INFLUENCE OF AMPHETAMINE (BENZEDRINE) SULFATE AND CAFFEINE ON THE PERFORMANCE OF RAPIDLY EXHAUSTING WORK BY UNTRAINED SUBJECTS*

E. E. FOLTZ, M.S., M.D., M. J. SCHIFFRIN, M.S., PH.D., AND
A. C. IVY, PH.D., M.D., CHICAGO, ILL.

IT HAS been reported[1-3] that amphetamine sulfate, d-desoxyephedrine hydrochloride and caffeine increase endurance to muscular work of the type that is performed by trained subjects during a hike or a march with a pack. Caffeine has been shown to increase the rate of recovery in trained subjects after an exhausting ride on the bicycle ergometer.[3] We desired to ascertain the effect of amphetamine and caffeine, given one hour before the work period, on the output of work in *untrained* male subjects doing rapidly exhausting work.

METHOD

Twenty-three untrained male subjects were used. They reported to the laboratory one hour before each first work period to take their capsules. These contained a placebo, or 10 mg. of amphetamine, or 0.5 Gm. of caffeine sodium benzoate and were indistinguishable from one another.

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.
Aided by the Abbott Fund of Northwestern University.

The work was done by having each subject step up on a 16 inch wooden stand with one leg and down on the same leg once every three seconds until he could no longer maintain this rate. Each subject carried a knapsack on his back which was loaded, to the nearest 5 pounds, with a weight equal to one-third of his own weight. Each subject would work to fatigue, rest for three minutes on a near-by bed, then work to fatigue again. This procedure was carried out three times on each subject with at least a day's rest in between. One time the subject received the placebo; one time he received the amphetamine; and one time he received the caffeine. The subjects were staggered so that at the end of each double work period approximately one-third of them had received the placebo, another one-third the amphetamine, and the other one-third the caffeine.

SUMMARY OF WORK EXPERIMENTS

(23 Subjects)

TABLE I

EFFECT OF DRUGS

	1ST WORK PERIOD		2ND WORK PERIOD		TOTAL WORKING TIME		% RECOVERY	
	RANGE	AVERAGE TIME	RANGE	AVERAGE TIME	RANGE	AVERAGE TIME	RANGE	AVERAGE
	seconds		seconds		seconds		seconds	
Placebo	60-371	189	55-304	107	124-629	296	14-95	61
Amphetamine	83-513	203	46-305	112	134-818	315	20-96	60
Caffeine	56-520	181	42-272	104	102-765	285	33-86	61

TABLE II

EFFECT OF TRAINING

	1ST WORK PERIOD		2ND WORK PERIOD		TOTAL WORKING TIME		% RECOVERY	
	RANGE	AVERAGE TIME	RANGE	AVERAGE TIME	RANGE	AVERAGE TIME	RANGE	AVERAGE
	seconds		seconds		seconds		seconds	
Experiment 1	56-251	142	42-184	84	102-411	226	20-91	63
Experiment 2	60-361	166	55-201	96	115-629	262	38-95	61
Experiment 3	102-520	265	69-305	144	178-818	409	30-96	59

RESULTS

The results are to be found in Tables I and II. In Table I are the data showing the results with the placebo, amphetamine, and caffeine. As is evident there is no significant difference between the three. In Table II are the data showing that the subject's work output improved with practice. It is evident, then, that training had a much greater effect on performance than did the drugs. It will be noted that the general per cent recovery remains very constant in both tables. Table II, however, shows a tendency for it to decrease as the work output of the first period increases, which is in keeping with what we have found to be true in the past.[3]

The drugs produced no side effects, except that they caused most of the subjects to report that they felt euphoric and as if they could do a "lot of work today." The euphoria, however, did not permit them actually to do more work of the type performed.

CONCLUSIONS

1. In this experiment the effect of training overshadowed any effect the drugs may have exerted. This type of test is inadequate to determine the effect of the drugs used on work output. The *experiment emphasizes the importance of training.*

2. The average per cent of recovery in this series is very constant.

3. The average per cent of recovery tends to decrease as the average work output of the first period increases.

THE INFLUENCE OF AMPHETAMINE (BENZEDRINE) SULFATE, d-DESOXYEPHEDRINE HYDROCHLORIDE (PERVITIN), AND CAFFEINE UPON WORK OUTPUT AND RECOVERY WHEN RAPIDLY EXHAUSTING WORK IS DONE BY TRAINED SUBJECTS*

E. E. FOLTZ, M.S., M.D., A. C. IVY, PH.D., M.D., AND C. J. BARBORKA, M.S., M.D., D.SC., CHICAGO, ILL.

INTRODUCTION

SINCE it was found by Foltz, Schiffrin, and Ivy[1] that practice or training overshadowed any effects that amphetamine and caffeine may have exerted on the work output of untrained subjects doing rapidly exhausting work, this study on trained subjects was undertaken. It has been shown that caffeine increases the rate of recovery from exhausting exercise in trained subjects.[2]

METHODS

Four medical students were used. They were provided with board and room in a hospital near the laboratory. Their food intake was under control; their diet was adequate in all known components, a certain variation in the selection of food items being permitted. The subjects were chosen on the basis of their willingness to cooperate, and not on the basis of muscular development, the work of the tests being their only source of physical exercise. The double work periods occurred on Monday, Wednesday, and Friday afternoons at the same time between 2 and 4 o'clock. The subjects worked on the bicycle ergometer described by Kelso and Hellebrandt,[3] at a rate of 1,235 kilogram meters (kg.m.) per minute, with a pedaling rate of 54 r.p.m.

*From the Departments of Medicine, and Physiology and Pharmacology, Northwestern University Medical School, Chicago.
Aided by the Abbott Fund of Northwestern University.

The periods of training of the subjects prior to performing these tests varied from three to sixteen months. The subjects worked to complete fatigue, rested ten minutes, and then worked to complete fatigue again.[2] The end point of fatigue was the point at which they could no longer hold the needle on the dial at the rate of 54 r.p.m.

The amphetamine (10 to 15 mg.), desoxyephedrine (5 mg.), and caffeine sodium benzoate (0.5 Gm.) were always administered intravenously. They were given at various times (thirty seconds to 30 minutes) prior to the first work period to determine their effect upon work output, and amphetamine and desoxyephedrine were given immediately after the first work period to determine their effect upon recovery, as measured here, from fatigue. The effect of caffeine upon recovery is reported elsewhere.[2] Placebo injections (sodium chloride solution) were given at random as controls. All solutions were colorless. The drugs were given intravenously to obtain rapid action, and because this group of subjects had previously obtained various therapeutic agents by a similar route to control the rate of absorption.

RESULTS

Various subjective sensations were reported by the subjects. After the injections of amphetamine, two subjects felt definitely "keyed up," and both experienced more leg pain during and after the work periods. The other two subjects reacted identically to both placebo and amphetamine. Desoxyephedrine seemed to increase the leg pain in one, to decrease it in another, and to cause insomnia in three subjects. In one case, when it was given immediately after the first period, it seemed to dispel fatigue. This sensation of being rested would last until he had worked for about ten seconds in the second period, when he would begin to feel as tired as though he had only had a placebo injection, and his recovery was not enhanced. This is in contrast to the response of this subject to 0.5 Gm. of caffeine sodium benzoate, given in the same manner.[2] This drug would also stimulate the subject, but the stimulation would last throughout the second period, and greatly increase his recovery. After being given either desoxyephedrine or caffeine for the rest of the day, this subject would feel extremely alert, and would experience difficulty going to sleep at night. One subject complained of weakness and giddiness following the first work period, after having received desoxyephedrine prior to working, and one reported no sensations from the desoxyephedrine. All four subjects reported definitely stronger immediate subjective sensations from the caffeine and desoxyephedrine when the drugs were given before the first period than when they were given after the first.

The results obtained by giving the drug before the first period are shown in Table I. It is evident that the amphetamine had no significant effect. However, desoxyephedrine and caffeine definitely increased the work output. With the increase of work done in the first period, the expected decrease in per cent recovery occurred.[1]

The results obtained by giving the drug immediately after the first period are shown in Table II. In the case of amphetamine it appears that the work output was enhanced. However, if this were true, the increment would

be in the second period work output and the per cent recovery would be higher than that of the controls. Because these qualifications are not fulfilled, no effect can be attributed to amphetamine. In the case of desoxyephedrine the per cent recovery was increased over that of the controls. However, if this were significant, certain other data should be present; namely, the first period work output of both the desoxyephedrine and the control series would be approximately the same, or that of the desoxyephedrine would be more; the second period and total work outputs would be significantly increased in the case of the desoxyephedrine. Since such is not the case, it cannot be said that desoxyephedrine significantly increased recovery.

TABLE I

DRUG GIVEN BEFORE THE FIRST PERIOD

SUBSTANCE	TRIALS	SUBJECTS	DOSE IN MG.	1ST PERIOD WORK OUTPUT (KG.M.)	2ND PERIOD WORK OUTPUT (KG.M.)	TOTAL WORK OUTPUT (KG.M.)	% RECOVERY
Amphetamine	10	2	10-15	4,570	2,862	7,432	63
Control†	10	2	----	4,793	3,117	7,910	66
Desoxyephedrine	12	4	5	8,870	5,750	14,620	66
Control†	12	4	–	7,055	5,105	12,160	72
Caffeine	6	4	500	5,805	3,911	9,716	66
Control†	6	4	–	5,201	3,667	8,868	70

TABLE II

DRUG GIVEN IMMEDIATELY AFTER THE FIRST PERIOD

SUBSTANCE	TRIALS	SUBJECTS	DOSE IN MG.	1ST PERIOD WORK OUTPUT (KG.M.)	2ND PERIOD WORK OUTPUT (KG.M.)	TOTAL WORK OUTPUT (KG.M.)	% RECOVERY
Amphetamine	17	4	10	6,764	4,167	10,931	63
Control†	17	4	--	6,478	3,931	10,409	62
Desoxyephedrine	31	4	5*	6,660	4,692	11,352	70
Control†	31	4	–	6,790	4,510	11,300	66

*In six trials less was used.

†Variations in the work outputs of the several control series result from different stages of training.

SUMMARY

The effect of amphetamine, desoxyephedrine, and caffeine upon work output, and the effect of amphetamine and desoxyephedrine upon recovery in subjects doing rapidly exhausting work have been observed. All three drugs stimulated some of the subjects mentally, so that they felt "keyed up" and more alert. The immediate subjective sensations resulting from desoxyephedrine and caffeine were much more pronounced when the drugs were given to a nonfatigued subject than when given to a subject following exhaustion. Amphetamine did not enable the subjects to work longer, nor to recover more rapidly. Desoxyephedrine did enable the subjects to work longer, when it was given before work began, but it did not hasten recovery when given to the exhausted subjects. Caffeine also enabled the subjects to work longer and, in addition, hastens recovery when given to exhausted subjects.[2]

CONCLUSIONS

As measured by this method:

1. Ten to 15 mg. of amphetamine injected intravenously do not increase work output in the trained subject doing rapidly exhaustive work.

2. Five milligrams of desoxyephedrine injected intravenously into the nonfatigued subject increase work output.

3. One-half gram of caffeine sodium benzoate injected intravenously into the nonfatigued subject increases work output.

4. Neither 10 mg. of amphetamine nor 5 mg. of desoxyephedrine injected intravenously into the fatigued subject actually enhance the rate of recovery from heavy work carried to the point of "exhaustion"; caffeine in adequate doses does.[2]

5. When stimulants are employed, they should be chosen according to whether it is desired to increase the work output of unfatigued subjects, or to enhance the recovery of fatigued subjects.

The drugs in some instances definitely improve subjective feeling tone and cause the subject to feel as though he can and is actually doing more work.

It should be remembered that the foregoing observations pertain only to rapidly exhausting work, and not to the type of work performed during a march or while standing guard.

PLANTAR REFLEX AS A CRITERION OF ENDURANCE*

PAUL I. YAKOVLEV, M.D., WALTHAM, MASS.

YOU HAVE just heard an authoritative and instructive discussion of the problem of fatigue and endurance by Dr. Dill. I am quite aware, therefore, that I am taking a measure of liberty in adding a few remarks of my own on the behavior of the plantar reflex following a prolonged locomotion as a criterion of endurance.

It is generally known that the Babinski sign or plantar extensor response of the big toe occurs as a result of a deficiency of the function of the corticospinal tract. It is usually taken as a sign of a grave disease; in fact, of a destructive lesion in the nervous system. Such a view, however, is incorrect. The extensor response of the big toe is normal in infants up to eighteen months of age. It is also elicitable in normal adults during a profound sleep. It is evident, therefore, that a Babinski sign need not imply necessarily a structural damage to the corticospinal tract, for it may occur in normal physiologic states. However, in individuals with a constitutional weakness or fragility of the nerv-

*Lecture XX, reprinted from *Collected Lectures* of the Seventh Postgraduate Seminar in Neurology and Psychiatry, first semester, Military Neuro-psychiatry, Metropolitan State Hospital, Waltham, Mass., 1942.

ous system, the Babinski sign occurs readily under varying conditions which ordinarily are insufficient to cause its appearance in the constitutionally well-endowed persons. It may occur, for example, after a prolonged exertion, such as a long march. I would like to make clear that potentially a Babinski sign may well develop in any individual if the amount of exertion and fatigue is brought to the point of severe exhaustion, or beyond that point. However, in the constitutionally inferior individuals it develops after a relatively small amount of exertion, insufficient to cause its appearance in normal people. The occurrence of a Babinski sign after an ordinary amount of exertion in a person otherwise appearing healthy is a cogent indicator of a constitutional inferiority of such a person, and may serve as a criterion of endurance. As a test of endurance it has the advantage of being technically simple.

The assertion of the significance of the "exertion Babinski" as a criterion of endurance is based on the following observations:

Three years ago Farrell and I[1] undertook to study the effect of exertion, and particularly of a prolonged locomotion on the plantar reflex in a group of young and healthy college graduates in a reserve officers' training camp, and in a group of the constitutionally inferior persons at a farm colony for mental defectives connected with Walter E. Fernald State School. The results were as follows:

In a group of 168 college graduates in a reserve officers' training camp the plantar reflex was examined before and after a march of fourteen miles during military maneuvers. Of the 168 men thus examined, a Babinski sign developed after the march in 12, or 7.2 per cent. In 10 of these young and otherwise healthy men, a Babinski sign developed unilaterally and in 2 bilaterally. Having thus obtained a relative measure of the effect of exertion upon the plantar reflex in a group of normal individuals, we have examined the plantar reflex before and after seven hours of ordinary farm work in a group of 229 adult imbeciles at the state colony. Of 229 mental defectives thus examined, a Babinski sign developed in 49, or 21.4 per cent. The incidence of exertion Babinski after a day of ordinary physical work in this group of constitutionally inferior persons was, therefore, three times that of its incidence in a group of college graduates after fourteen miles of forced march.

Effect of locomotion. When a group of 60 mental defectives selected among those in whom after a day of ordinary farm work the Babinski sign did not develop were put to a test of a march of ten miles, 13 per cent of them developed a Babinski sign. After a march of an additional fourteen miles, 23 per cent developed a Babinski sign. It should be evident that locomotion was a particularly effective mode of exertion, causing the Babinski sign to appear in certain predisposed individuals.

The incidence of an "exertion Babinski" is as high in individuals presenting other evidence of constitutional inferiority. Thus, last summer Semrad and I[2] examined the plantar reflex in 64 adult males with various forms of chronic psychoses, chiefly schizophrenia, before and after a walk of only six miles. After the walk 10 per cent developed a frank Babinski sign unilaterally or bilaterally.

When the factors underlying the occurrence of "exertion Babinski" were investigated closer, interesting facts came to light. It was found that the individuals who endured a prolonged locomotion *without developing a Babinski sign* showed a relatively normal time of development of locomotion in infancy. They walked at about the normal age of *one and a half years.* On the contrary, the individuals *who developed a Babinski sign* after exertion began to walk much later, namely, at an average of *two and a half years of age,* and those of them *who developed a bilateral Babinski sign* were the most delayed in the age of establishment of erect locomotion, for they learned to walk on the average as late as at *three and a half years of age.*

It should be quite evident, therefore, that in certain individuals the occurrence of Babinski sign under influence of exertion stands in direct relation to their constitutional endowment. It appears to be a pertinent indicator of the constitutional stamina of the individual. I believe this fact is of a distinct practical interest for military medicine. A soldier who after a march of a few miles or at the end of a day of routine work develops an extensor response, especially a bilateral Babinski sign, regardless of his intellectual and physical status otherwise, should be considered a poor choice for an assignment to special task units in which physical endurance is a prime requirement, although this limitation does not preclude such a soldier to be proficient in other military services.

Concluding, I would like to emphasize that the occurrence of "exertion Babinski" has nothing to do with the "intelligence" of the individual. It may occur in mentally normal and physically healthy college graduates as well as in imbeciles and in psychotic individuals, although in the latter groups it occurs more readily and more generally than in the former group.

MILITARY ASPECTS OF ALLERGY*

CAPTAIN PHILIP BLANK, M.C., U. S. ARMY

THE advent of drafting men into the armed forces has brought with it the problem of allergy to confront the Army Medical Corps. Until now, problems involving allergic diseases have been minimized by the simple expedient of refusing to admit into the service all men with a history of a major allergy, and by discharging from the service those persons whose allergic problems became too troublesome. However, man power is important; it must be conserved and it must be utilized as advantageously as possible. The drafting of class IB men increases the problem of the conservation of man power, and the allergist is participating in the solution of this problem by aiding in the treatment and assignment of these physically inferior men to places and duties that will utilize to the greatest extent possible their abilities, and at the same time release for combat duty those men who are physically able to do the more arduous work.

In World War I the specialty of allergy was too new to attempt the solution of so vast a problem as was presented at that time. Allergy then had no official recognition, nor is it recognized officially by the Army at present. The result is that we possess rather poor statistics for most allergic diseases treated during the period previous to the present war. Fairly adequate statistics on asthma alone are available in Volume 15 of the statistical report of the Army Medical Department.[1]

During the last war the draft board rejections for asthma with emphysema and bronchitis averaged 2.45 per 1,000.[2] It should be noted, however, that not all asthmatics were included in this category, since associated emphysema or bronchitis was necessary for rejection. In the Army between April, 1917, and November, 1919, approximately 2.62 white soldiers per 1,000 and 5.60 colored soldiers per 1,000 were admitted to hospitals with the diagnosis of asthma; and 2,948 soldiers were discharged for disability arising from that defect. This represents 5 men per 100,000. Asthmatic cases caused the loss of 190,273 days. During World War I only 2 men per 1,000 were diagnosed as asthmatic, whereas fifteen years later 12 per 1,000 were receiving compensation for this ailment.

Since World War I the field of allergy has grown to such a proportion that it is now capable of dealing with questions of allergy as a distinct military problem. Thus, in place of the inadequate treatment of the past, allergic diseases are now diagnosed and adequate treatment is attempted. Reclassification is substituted for over-all discharges, and conclusions based on inadequate information are replaced by decisions having their foundation in known and proved data.

---

*From the Station Hospital, Fort Eustis, Virginia.

In World War II the latest statistics furnished by the office of the Surgeon General[3] indicate an annual admission rate of 2.57 per thousand per annum for allergic disease, the certificate of disability discharge rate is 0.40 per thousand per annum, and the death rate is nil.

From these statistics of World War I and II it is evident that the problem of allergy is not a small one and, considering its nature, very difficult.

The military aspect of allergy resolves itself into three separate problems. The first concerns itself with the professional duties of the Army allergist; the second with the correct distribution of allergists in the tables of organization of the medical department; and the third with the formulation of specific physical standards for all major allergic disorders.

The professional duties of the Army allergist deal with the diagnosis and prognosis of allergic diseases. A discussion of the routine methods of diagnosis used in the field of allergy does not fall properly within the realm covered by this dissertation. However, the prognosis of the ability of the allergic soldier must be considered, and it must be emphasized that this is the most important single task of the Army allergist. He, while attempting to perform this task successfully, must discover the answers to numerous and perplexing questions. Is the soldier fit for duty or should he be rejected or discharged? If fit for duty, does this mean full duty or limited service? If the conclusion is that the man is suited for limited service only, what are the services he is capable of performing and where can he perform them to the best of his abilities?

Not only is the allergist capable of handling the major allergies, such as asthma and hay fever, but his services are of indispensable value to the dermatologic, eye, ear, nose, and throat sections of his hospital. It is he who should investigate and control the contact skin problems, especially those cases involving poison ivy and "laundry dermatitis." Furthermore, many cases seen in these departments will respond promptly to an allergic regime but not to ordinary methods of treatment.

Inasmuch as the amount of serum and vaccine therapy is extremely great in the Army, the supervision of these therapeutic measures is a duty which should fall in the realm of the allergist. It is well known that all soldiers receive typhoid, smallpox, and tetanus prophylactic measures. If indicated, yellow fever, typhus, and cholera prophylaxis are administered. Methods of administration and control of reactions require constant supervision in order to minimize untoward reactions.

It is obvious that the correct distribution of allergists in the Army is of prime importance in the conservation of the material and men needed to carry on this type of work. Since the most important work of the allergist is concerned with the prognosis of a soldier's ability, it becomes evident that the allergist is best able to perform his duties where troops are inducted and trained. However, under the present organization of induction and reception centers, little time is available to the allergist to permit him to do more than eliminate those men who have no military value. It is rather at the training centers that the soldiers first come into contact with actual Army activities for

a period sufficient in duration so that they may be studied, their symptoms may be evaluated, and disposition of their cases may be made. Large general hospitals should also have allergists to take care of the allergic diseases discovered in the forward echelons.

The problem of allergy in the Army is further complicated because as yet adequate standards covering the allergic diseases have not been formulated by the Army Medical Department. This does not necessarily reflect adversely on the medical branch of the Army, but rather on the newness of the field of allergy. The formulation of an adequate allergy department must proceed slowly and must await the results and statistics uncovered by those medical officers sincerely interested in this field.

From a communication of the Surgeon General's[3] office regarding the physical requirements pertaining to the person suffering from an allergic disease, the following is taken:

"The physical standards for admission to the Army make no reference to specific allergic conditions other than hay fever. Individuals with mild hay fever are accepted for general military service, those who have moderate hay fever are accepted for limited military service, and those who have severe hay fever are rejected. Other important allergic conditions may be disposed of as indicated in Paragraph 5 *a* MR 1-9, revised October 15, 1942, which reads as follows:

'If any individual is regarded by the medical examiner as physically unfit for military service by reason of physical or mental defects not specifically noted in these regulations, he will nevertheless be recommended as unsuitable for general service or for limited service as the case may be. A brief statement of the reasons for the rejections will be entered on the report of physical examinations. So far as practicable, however, the physical classification of individuals will conform to the specified requirements.' "

To illustrate the problem of allergy in the Army, the statistics obtained at the allergy clinic at Fort Eustis, Virginia, from June 1, 1941, to October 1, 1942, are here presented and evaluated.

Table I represents the total number of cases seen at the allergy clinic and includes both outpatients referred to the clinic by the various infirmaries on the post and the hospitalized cases. No effort has been made to include in the tabulation those soldiers seen at the various infirmaries who were not sent to the clinic. The figures regarding the hospital cases were taken from the official diagnosis file kept by the registrar of the hospital and represent only those cases with the primary diagnosis as stated.

The total number of cases observed at the clinic represents approximately 1.5 per cent of all personnel at this post. It should be noted that this estimate is lower than is usually quoted; however, it is not a completely accurate reflection of the situation because undoubtedly many soldiers afflicted with minor allergies did not report to the infirmary or were not referred from the infirmary to the clinic. We may anticipate that over 1 per cent of all men entering the Army will require allergic care.

A perusal of the table indicates that the respiratory problems form the largest group among the allergic diseases; in fact, slightly over half of all allergic cases observed belong in this category. The greatest number of cases in this respiratory group are those of seasonal hay fever, these representing

slightly less than half of the total respiratory cases and 22 per cent of all allergic problems. The ragweed pollen cases far exceed those involving grass pollen; only a very few tree pollen cases have found their way to the allergy clinic. It is encouraging to realize that all the hay fever cases constitute a group for which excellent therapeutic results may be expected with only a moderate loss of man hours. The problem is still further simplified because there is a definite territorial ragweed belt. This belt is confined mainly to the areas of continental United States and Canada east of the Rocky Mountains (short and giant ragweeds), and thus all ragweed cases will be free from ragweed hay fever so long as they remain outside this area.

TABLE I

STATISTICS OF THE ALLERGY CLINIC, STATION HOSPITAL, FORT EUSTIS, VA. FROM JUNE 1, 1941, TO OCTOBER 1, 1942

TOTAL CASES OBSERVED	NUMBER OF CASES	% CASES	HOSPITAL CASES	C.D.D.* CASES	ADMISSION RATE§ PER 1,000	RATE OF C.D.D.* PER 1,000

*Certificate of disability discharge.
†Not classified according to this diagnosis.
‡One case transferred to Walter Reed General Hospital.
§Admission rate to clinic per 1,000 men on post.

The policy of this clinic regarding these cases has been to continue treatment of all persons who have previously received medical care for this disease. Many cases have been treated preseasonally or perennially prior to induction into the Army. The cases of mild severity have been treated symptomatically with eye drops, nose drops, or ephedrine by mouth as is indicated. The moderately severe and severe cases are treated coseasonally with small doses intradermally accompanied by symptomatic treatment. Almost all these soldiers were treated in an ambulatory fashion; only four cases were hospitalized. Those men who suffer severely were instructed to secure perennial treatment as long as they remain in the ragweed belt. The results of therapy have been exceedingly gratifying.

Although the asthmatic group represents only 15.7 per cent of all allergic cases observed, this group nevertheless poses the most difficult problems. It is here that the allergist must be extremely perspicacious in order to attain correct disposition of the case. It is our opinion that practically all asthmatics, except those of mild seasonal type, should be reclassified into limited service.

In our clinic we have divided our asthmatic patients into four classes: first, the seasonal asthmatics; second, the old chronic asthmatics with or without secondary complications who have never been capable of pursuing a civilian occupation without a great deal of lost time; third, mild asthmatics who have been able to accomplish useful work in civilian life without undue loss of time; and fourth, those asthmatics who have had their first attack while in the Army. The seasonal asthmatics are treated similarly to severe hay fever cases, and no doubt can do well in foreign service, especially with noncombatant units. Old chronic asthmatics with secondary complications should be discharged from the service as soon as the diagnosis is made. Therapeutic results with this class are very unsatisfactory under military conditions. Asthmatics who have never been successful in civilian employment can hardly be expected to be of any greater value in military service. Thus, it is extremely beneficial both to the Army and to these men that they be discharged as promptly as possible. Those asthmatics without complications who have been able to follow a vocation in civilian life without undue loss of time are reclassified for noncombatant duties. The positions to which they are assigned should simulate their civilian occupations as closely as possible. These men can be hyposensitized and a rather moderately effective allergic regime can be instituted because their reclassification into noncombatant units makes treatment possible. Territorially, these men can be restricted to specific areas.

The last class of soldiers suffering from asthma includes those persons whose cases in the asthmatic group are the most difficult to handle. These men have had no or few previous attacks. They generally possess a past history of some allergic manifestation and a familial history of allergy. These cases should be skin tested for those materials which they now encounter in their new Army environment. One must always keep in mind the high concentration of certain substances in the barracks, e.g., feathers, tobacco smoke, mattress, blanket, and wood dust. Experience at this clinic has indicated that barracks dust is much more antigenic than ordinary house dust, and we have attributed this condition to the above-mentioned factors. It has been found that many patients allergic to barracks dust respond promptly to a coseasonal type of treatment, i.e., small frequent doses intradermally. If such measures do not evoke rapid and proper response from these men, they should be reclassified. Trials of duty are essential in forming an opinion in these cases. If the patients become progressively worse, they should be discharged from the service.

The remaining cases in the respiratory group may be termed harassing diseases. Persons falling in this category are frequently on sick call or are attending the ear, nose, and throat clinic. Many of these cases can be controlled by the judicious use of ephedrine drops, others by the elimination of the offending inhalant or by hyposensitization to the antigenic substance.

Nasal and sinus polyps may require surgical removal. Nevertheless, they should be examined from an allergic aspect and, if feasible, measures should be taken to prevent their recurrence.

The second large group of cases with which the allergy clinic is confronted consists of the dermatologic allergies. As might be anticipated, the cases of contact dermatitis occupy the predominant position. In this group the most habitual offender is poison ivy, and the parts of the body usually affected are the hands, arms, legs, face, and penis. The most efficacious therapeutic measure which should be instituted is prophylaxis, which is extremely simple because it can be accomplished by the use of material available to all soldiers—G. I. soap. If persons who are aware of their susceptibility to plants, or who know or suspect they have contacted poison ivy, will merely bathe with G. I. soap as soon as possible after contact, making certain to wash the parts of the body most frequently affected, much of the dermatitis venenata due to poison ivy will be eliminated. It must be emphasized that overtreatment of these cases produces unfortunate results. The value of the injectable extract of poison ivy twenty-four to forty-eight hours after contact is questionable, and is too costly for routine use beforehand. Most posts will have fewer casualties from this disease if by cooperative efforts of the allergist and post medical inspector there is an intelligent mapping and clearing of areas known to have poison ivy.

Wool is another important irritant. To determine whether or not a patient is sensitive to this material, a patch test, consisting of a patch of the wool underwear or shirt the soldier has been wearing, is used. However, such a test does not eliminate "laundry dermatitis." As has been reported in a previous article by the author,[4] the majority of our so-called "wool dermatitis" cases have been caused by laundry soaps and more recently by waterproofing fluid. "Laundry dermatitis" occurs more often where thick fabrics are involved, because, if woolen and cotton articles are subjected to an equal amount of rinsing, a greater proportion of the laundry materials used in washing will remain in the heavier than in the lighter garments. By enlisting the aid of the laundry officer so as to insure more thorough rinsing, the so-called wool dermatitis cases drop remarkably.

Other objects giving rise to contact dermatitis are the aluminum in the identification disks worn by the soldiers, the metal parts of watches, and the plastics used as wrist bands. There was one case of ulcerative stomatitis which was due to sensitivity to dentures, the patient being sensitive to all types of dentures except vitallium.

Urticaria is probably much more frequent than the reported figures would indicate because of the great number of vaccine injections administered in the Army and the drastic transformation undergone by a man who changes his status from civilian to soldier. This is because most of the hives are quite evanescent. The majority of the cases of hives seen at the clinic are those that have either lasted several days or are of the persistent or recurrent type. Most of those in the nonpersistent group clear quickly, but those of the recurrent type offer a very difficult diagnostic problem inasmuch as many cases are not allergic in origin. Other factors must be sought, especially those of a neurogenic character. It is rather astounding to note how much a chaplain's per-

sonal conversation with a patient, when accompanied by a little sedation, can accomplish in the way of alleviating a case of hives on a functional basis.

Atopic dermatitis cases should be handled in much the same way as the asthmatics. If a case is mild, tar ointments and moderate control will result in marked improvement; if moderate, the patient should be reclassified. The latter cases require definite allergic regimes and therapy which can only be given in the rear echelons. The severe cases should be discharged from the service, and this should certainly be the solution adopted after a trial of therapy and a trial of duty result in little or no improvement. Throughout any discussion of allergy in the Army, it must be remembered that each soldier represents a financial investment to the Government, and if the return on the investment does not warrant the expenditure, the sooner the financial operation is terminated the better for all concerned. It must also be recognized that of all the diseases, except venereal, confronting the Army, the dermatologic ones can destroy the morale of soldiers more rapidly than any other group of diseases. Men are exceedingly sensitive to deformities and to skin disorders both in themselves and in others. Thus, it is often wise to transfer from combat branches to service units those persons possessing unsightly skins if the skin disorders are of a permanent or semipermanent nature. This will prevent the disintegration of morale among the fighting divisions of the Army where morale is especially vital.

Dermatophytids of the hands are quite common in the Army, but they should be differentiated from other lesions, such as nummular eczema, contact dermatitis, and psoriasis. However, once dermatophytids are recognized, they respond exceptionally well to local treatment of the original lesion accompanied by intradermal doses of the fungus extract for the purpose of hyposensitization.

Many examples of drug allergies are seen at the post and these are especially noticeable in the wards of the hospital. At present, the sulfone drugs cause the most trouble. Cases involving drugs rarely represent an allergic problem except as a matter of diagnosis, and the diagnostician is hindered by the lack of good methods of testing. It is hoped that the latter problem will soon be solved by a more effective testing procedure than is presently employed.

Although the ophthalmologic allergies represent only a small group of the allergic diseases observed at our clinic, they are nevertheless quite fascinating. It should be noted that we have reported separately only those cases in this group devoid of concomitant symptoms. Thus, where conjunctivitis has been accompanied by hay fever, rhinitis, or asthma, the statistics have been included under the specific headings of the respiratory allergies. The majority of the cases of conjunctivitis were due to pollens and dust. Conjunctivitis may also be classified as an harassing disease because it leads to much physical discomfiture and thus decreases the efficiency of the soldier. Most conjunctivitis cases respond well to hyposensitization, but overdosage must be carefully avoided as keratitis may result. We have found small intradermal doses, combined with local treatment, to be most satisfactory.

As we have previously reported,[4] an unusually large number of ulcerative keratitis cases have been observed at this clinic. The clinical picture is that of small superficial ulcers located around the circumference of the cornea about

1 or 2 mm. from the limbus. These ulcers are very small and shallow, and are usually multiple; with progression they increase in size and coalesce and may form a continuous marginal ulcer. Marked conjunctivitis accompanies the keratitis. While pain is not usually present, itching may be intense. Central keratitis sometimes occurs secondarily due to lack of nourishment. Most cases respond well to hyposensitization, but hospitalization is indicated.

The gastrointestinal cases and the other minor allergies constitute interesting diagnostic situations for the allergist, but they are not significant as a military problem because of the small number of cases involved.

The statistics of the Station Hospital at Fort Eustis, Virginia, reveal that 1,833 cases were observed at the allergy clinic. This represents an admission rate to the clinic of 15 men per thousand for allergic study, treatment, and disposition. Slightly over 20 per cent of these cases were admitted to the hospital, or about 3 men per thousand were hospitalized for allergic disease. This figure compares favorably with the admission rate quoted earlier from the office of the Surgeon General of 2.57 per thousand. It must be noted, however, that as only a small proportion of the cases of major allergy were admitted to the hospital, the problem is actually much larger than is indicated by the admission rates to the various hospitals.

The total number of men discharged from the Army at Fort Eustis as being unfit for any military duty is 78, which represents 4.3 per cent of all cases seen at the clinic, or 0.60 men per thousand on the post. This also compares favorably with the certificate of disability rate of 0.40 per thousand, as reported by the office of the Surgeon General.

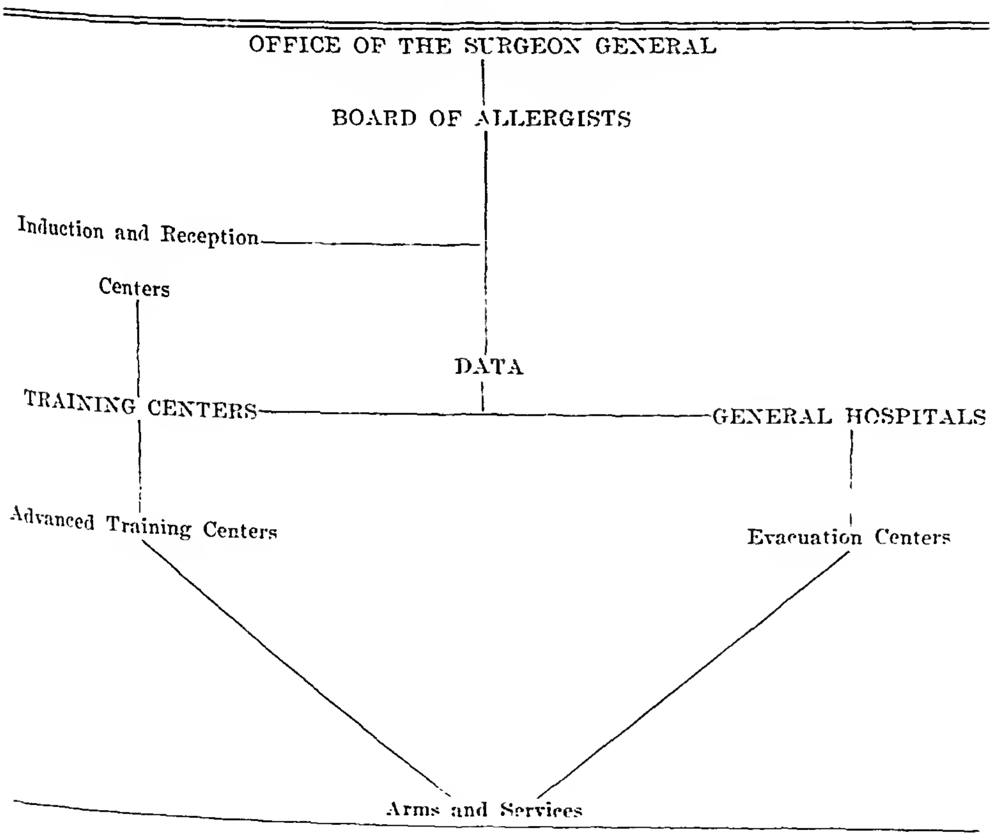
This dissertation is an attempt to present a comprehensive analysis of the military aspects of allergy in the Army. The study has led me to suggest the organization of the Army allergy service. I do not profess to possess the qualifications needed to set up the vast organization which would be required to take care of the thousands of men in the Army of the United States who suffer from allergic diseases, but I rather offer this suggestion with the hope that it will be of some constructive assistance in the solving of the problems of allergy in the armed forces.

The training camp is the focal point in the organization of Army allergy. As has been previously stated, training camps present the allergist with the first real opportunity to observed adequately the allergic patient. The allergist at such camps should be well trained not only in the routine diagnostic and therapeutic measures pertaining to allergy, but he should also have available all pertinent information concerning possible allergic factors present in all theaters of operation and in all branches of the arms and services. If persons suffering from allergic diseases are adequately dealt with by such specialists, the problem of allergy in forward echelons would be of slight significance.

However, it is inevitable that the allergic diseases of some persons will not manifest themselves until after the soldiers have left the training centers. Such cases can best be handled at the large general hospitals where competent allergists should be stationed. There the duty of the allergist should include the routine care and disposition of allergic patients, and it also should be incumbent upon him to collect pertinent data relating to the various allergic

factors of those areas which his hospital services. These data then could be gathered by a board or committee of allergists in the office of the Surgeon General, and subsequently evaluated and distributed to the various hospitals having an allergy service. Thus, without the necessity of maintaining a large organization, it would be quite simple to collect and to disseminate significant information concerning allergic factors present throughout many areas. The function of such a board or committee would be not only to correlate scientific data relating to allergic diseases but also to standardize material and procedures to be used in the diagnosis and treatment of allergic cases. Testing material would conform to specific standards, thereby eliminating variations found in the different extracts now being utilized. Accompanying the standardization of diagnostic procedures would be the realization that military needs must be of primary consideration. In this way, adequate and reliable data can be compiled, evaluated, and used for the purpose of solving the problem of allergy in the Army. Chart 1 diagrammatically represents the organization described.

CHART 1



As military allergy gradually becomes more comprehensible, definite physical standards for admission into the Army can be promulgated. The use of such standards would eliminate the necessity of having highly trained allergists present at induction centers. With the passage of time the field of allergic

diseases assumes greater importance in medicine. It thus becomes incontrovertible that the problem of allergy is one that must be met and solved.

SUMMARY

From this article, which is an attempt to analyze the problem of allergy confronting the Army Medical Corps, certain conclusions may be drawn.

1. Over 1 per cent of all soldiers entering the armed forces require allergic care.
2. The problem of allergy in the Army may be divided into three categories:
   a. The professional duties of the Army allergist.
   b. The organization of an allergy section in the Army Medical Corps.
   c. The formulation of specific physical standards for all major allergic diseases.
3. The professional duties of the Army allergist consist of:
   a. Diagnosis and prognosis of the capabilities of the allergic soldier.
   b. Treatment of allergic cases giving sufficient consideration to the allergic problems which confront the ophthalmologic, otorhinolaryngologic, and dermatologic sections of the Medical Corps.
   c. Supervision of vaccine therapy.
4. The organization of an allergy department is suggested. This organization should consist of first, a board of allergists to control activities, to collect, correlate and disseminate pertinent data and to standardize all material and procedures to be used in the allergy department; second, allergy sections should be established at training centers and general hospitals, the former to prognosticate and classify allergic patients according to their capabilities, and the latter to collect significant data relating to the district they service and to handle cases arising after soldiers leave the training centers.
5. Inasmuch as the board at the office of the Surgeon General is the only body having available to it all the statistics regarding allergic diseases in the Army, it is that board which should formulate the specific physical standards to guide these Army physicians seeking to arrive at a solution of the problem of Army allergy.

HEART DISEASE IN MIDDLE AGE*

LIEUT. COM. CHRISTOPHER C. SHAW, M.C., U. S. N. R.

IT HAS been said that "life begins at forty" but it might better be said that "life begins to go downhill at forty," for heart disease resulting from degenerative changes in the cardiovascular system is the most common, single cause of death and disability in the middle-age group between 40 and 65 years.[1] Disorders of the cardiovascular system which occur during middle life may be classified under three main headings:

1. Heart disease caused by infectious agents.
2. Heart failure resulting from metabolic and endocrine dyscrasias.
3. Cardiovascular disorders due to degenerative processes.

Within the first division one finds lesions of the cardiovascular system resulting from typhoid fever, syphilis, diphtheria, scarlet fever, bacterial endocarditis, glomerulonephritis, pyelonephritis, tuberculosis, and lead poisoning.

Of these infectious diseases involving the heart and blood vessels during middle age, syphilis is of prime importance. The Spirochaeta pallida attacks the myocardium and aorta and larger arteries in the general systemic invasion which follows shortly after the initial lesion, or chancre, appears. The organisms are distributed throughout the body and remain quiescent in the cardiovascular tissues during the long period of latency which precedes the onset of tertiary syphilis. When the signs and symptoms of cardiovascular lues appear they may develop with almost explosive violence.

The pathology in the myocardium consists of either a diffuse inflammatory involvement of cardiac muscle tissue with progressive congestive failure or the development of gummata with destruction of the intrinsic nervous pathways and subsequent arrhythmia, often in the form of heart block. The diffuse myocarditis alone may be a cause of sudden death in middle age.[2]

Invasion of the arterial tree by the spirochete of lues centers about the root of the aorta and begins as an obliterating arteritis of the vasa vasorum with subsequent necrosis and degeneration of the media of the aorta (a mesaortitis). This process continues and may cause formation of an aneurysm, or produce insufficiency of the aortic valve, or encroach upon the ostia of the coronary arteries which arise in the sinuses of Valsalva.

Aneurysmal dilation of the aorta may be either saccular or fusiform but in either case places practically no burden on the heart. Aneurysms cause symptoms only when they erode bone—ribs, vertebrae or sternum—or impinge upon vital structures in the mediastinum. Their presence, however, is a harbinger of death due to the danger of rupture with sudden exsanguination, or

*Reprinted from U. S. Nav. Med. Bull. 40: 579 (July), 1942.

the possibility of slow hemorrhage from necrosis and perforation of the aneurysmal wall. Insufficiency of the aortic valve and coronary stenosis produce typical clinical syndromes and require no further elaboration at this point.

Unfortunately for the patient and for the clinician, cardiovascular syphilis frequently develops in the presence of a negative Wassermann so that the diagnosis (and treatment) cannot be established by serologic tests. This probably occurs in 15 per cent to 20 per cent of luetic patients with cardiovascular syphilis, and is most likely the result of inadequate therapy during the primary and secondary stages of the disease. The treatment received was sufficient to reverse the positive Wassermann at that time but insufficient to prevent the development of cardiovascular involvement 10 to 20 years later, in spite of the fact that the patient's blood serology continued negative. In such instances, the doctor must lay great stress on the history of venereal infection and specific antiluetic therapy in youth and not be guided too strongly by repeatedly negative blood reports during middle age. Treatment should be directed toward alleviation of the congestive failure first, and then supplemented by careful administration of spirocheticidal drugs. The prognosis is poor in any form of cardiovascular syphilis.

With the exception of disease of the thyroid gland, metabolic and endocrine disturbances such as gout, obesity, pituitary, and adrenal tumors are relatively rare in older pilots and for this reason will not be considered in this discussion. Thyrotoxicosis, however, produces certain disturbances in the circulation which are worthy of comment.

The increase in metabolism due to an altered or toxic secretion of the thyroid hormone whips up the general circulation, causes slight peripheral dilatation, and increases the pulse pressure. The metabolism of the heart muscle itself is also elevated and results in a marked rise in the pulse rate with proportional decrease in the length of the diastolic phase of the cardiac cycle. The combination of these factors throws a tremendous load on the myocardium which will eventually show signs of congestive failure unless and until the toxic secretion is reduced by administration of iodine and then ablated by subtotal thyroidectomy.

In deficiency of the thyroid gland the patient becomes myxedematous, and as a result of the lowered metabolism the myocardium becomes soft and flabby and sluggish and unable to maintain an adequate circulation. Congestive failure will result but can be promptly mended by administration of thyroid extract by mouth. The basal metabolic rate is an index of diagnosis and of adequate thyroid medication in such cases. Sudden cardiac death has been reported in untreated myxedematous patients.[2]

Finally, mention must be made of the importance of masked hyperthyroidism in heart disease.[3] This possibility should be borne in mind in all cases of congestive failure which fail to respond to bed rest and adequate doses of digitalis. Such patients often exhibit transient auricular fibrillation, nervousness, loss of weight, tremors, and excessive perspiration and yet they present no exophthalmos nor enlargement of the thyroid gland. Blood pressure readings, pulse pressure, and pulse rate are frequently found to be within normal

limits in spite of the dyspnea, cyanosis, and edema which alarm the patient and confuse the physician. Low-grade glycosuria and mild diarrhea may also be present.

The basal metabolic rate in such cases will be elevated to +30 or even to +70 and will determine the true cause of the failure of the heart.[3] When masked hyperthyroidism is engrafted upon a heart already embarrased by previous disease—rheumatic fever with mitral stenosis or coronary occlusion with infarction—the differential diagnosis requires clinical acumen of a high order. The first syndrome may dovetail into and almost completely obscure the second. When the two conditions are found to coexist—based on repeated basal metabolic rate determinations—treatment should be directed toward the control and removal of the "masked" thyrotoxicosis.

By far the largest and most difficult field of heart disease in middle life comes under the heading of the "degenerative processes." This is especially true since the exact cause, or causes, of vascular degeneration are not known. However, because of the magnitude and importance of the problem, a short review of the salient points may not be amiss, even though our present knowledge of the subject is far from complete.

Degenerative diseases of the cardiovascular system include arteriosclerosis, coronary disease and angina pectoris, hypertension, and hypertensive heart disease. In this same category most authors include *cor pulmonale* and chronic nonvalvular heart disease, or chronic myocarditis.

Recent studies indicate that the underlying factors in all these degenerative states are heredity and the wear and tear of existence caused by the physical, mental and nervous strains of living and making a living in the twentieth century. The adage, "a man is as old as he feels," might be more truthfully paraphrased to read, "a man is as old as his arteries," that is, as old as the quality and function of his vascular tree inherited from his ancestors.

At the present writing, medicine has no control over heredity, although it is constantly striving to patch up inherited defects. By the same token, little can be done to control the speed of modern living or to lessen the wear and tear on the cardiovascular system incident to high-speed flying in modern military aviation. Both the strain and the stress are plunging forward at relatively increasing velocities and show no immediate evidence of reaching a reasonable equilibrium. And the cardiovascular system pays the piper in the long run. Sometimes the nervous system goes bankrupt first; but even in this case, the scars of battle have already left their indelible mark on the heart and blood vessels.

The most frequent "mark" is the atheromatous plaque of arteriosclerosis which is a manifestation of senescence of vascular tissue. The underlying cause probably will be found in a faulty metabolism of cholesterol, as it has been shown that the cholesterol content of the thoracic aorta increases with age.[4] This degenerative process termed "atherosclerosis" may be general in distribution involving all the arteries of the body from the largest to the very smallest, or it may be localized in one or more specific areas such as the brain, the coronary vessels of the heart, or in the kidneys.

As the vascular degeneration progresses, there develops a relative ischemia of the tissue supplied by the atherosclerotic vessel. If the process is gradual, a more or less efficient collateral circulation may be established which will serve to mask for a time the insidious and progressive nature of the atheromatosis. On the other hand if the diminution of blood flow to a part or organ be sudden or complete, as in thrombus formation over an ulcerated sclerotic plaque or in fracture of a calcified atheroma with embolic phenomenon, then infarction of the tissue peripheral to the sudden occlusion results. In either instance the end picture is primarily a diffuse or localized fibrosis of the parenchyma.

Vascular degeneration in the brain caused by atherosclerosis gives rise to the signs and symptoms of cerebral arteriosclerosis. In the kidney the disease may remain quiescent until the rather sudden onset of marked renal impairment or progressive renal insufficiency appears.[2] Arteriosclerosis of the vessels supplying the pancreas gives rise to a true diabetes which is usually comparatively mild. In the extremities the process produces causalgia and intermittent claudication. Thrombosis and/or embolism rapidly lead to gangrene.

Arteriosclerotic aortitis is usually symptomless until the process invades the ring of the aortic valve causing stenosis, or unless the coronary ostia in the sinuses of Valsalva are impinged upon by atherosclerotic plaques. An aneurysm of the aorta due to arteriosclerosis may be a simple, diffuse, silent dilatation or it may occur as the dissecting type which is spectacular, excruciatingly painful, and usually causes sudden death from shock or from rupture of the aorta in a few hours or days after the sudden and dramatic onset of the dissection of the media.

Atheromatosis of the coronary vessels leads to coronary insufficiency and occlusion with impaired cardiac efficiency due to myocardial ischemia and infarction. In this connection it is interesting to point out that coronary occlusion *per se* does not necessarily produce any characteristic clinical manifestation.[5]

If the occlusion develops very gradually (as it may in atherosclerosis), nature will improve the opportunity to develop or expand the potential collateral circulation in the heart muscle and produce anastomoses sufficient to prevent, or circumvent, infarction of the myocardium. This is brought about by opening of the Thebesian capillaries coursing within the muscle bundles and by the propagation of vessels from the circulation of the pericardium at its attachment near the base of the heart.

The extent and efficiency of this collateral circulation have not been generally realized, but its importance is evidenced by the fact that it is found operative in approximately one-fourth of the patients with coronary occlusion.[1] Their lives have been prolonged for years and they may have remained symptomless because of the very chronicity of their vascular degeneration. At postmortem examination extensive atherosclerosis of the coronary vessels may be present out of all proportion to the clinical manifestations.[6] Cases are on record in which one or both coronary arteries have been found completely occluded at autopsy, yet the patient remained free of symptoms referable to the heart during life and succumbed from noncardiac causes.[1]

If, on the other hand, the occlusion occurs rapidly, the classical picture of myocardial infarction develops. This is characterized by substernal pain and oppression due to anoxia of the infarcted area of heart muscle.[7] There is concomitant fall in blood pressure, pallor, shock, fever, leucocytosis, pericardial friction rub and typical electrocardiographic changes. In such cases the clinical diagnosis is usually coronary thrombosis, but the term "myocardial infarction" would be more accurate.

Pain is commonly an outstanding symptom of this syndrome and frequently is crushing or grinding in severity and of prolonged duration. In other cases pain may be notable by its absence, since there are certain areas along the lateral wall of the left ventricle which are relatively silent as far as symptoms and signs and electrocardiographic evidence of infarction are concerned. Many cases of painless myocardial infarction have been recorded in which the only complaints were sudden dyspnea and progressive congestive failure.[8]

Sclerosis of the peripheral vessels is not a true cause of heart failure, for it has been shown that extreme degrees of peripheral arteriosclerosis have no deleterious effect on cardiac function;[3] nor is there necessarily any relationship between peripheral and coronary vascular degeneration. The former may exist in the entire absence of the latter, and, conversely, coronary atheromatosis may be present to the point of death and show no evidence of narrowing or tortuosity or induration of the peripheral arteries, nor of the retinal vessels in the fundi. The term "arteriosclerotic heart disease" is, in a sense, a misnomer and should be dropped in favor of the more truly descriptive phrase "coronary artery heart disease."[3]

Angina pectoris manifested by substernal or precordial pain of agonizing character and short duration is a symptom complex and not a disease entity. It is the consensus that it results from anoxia of the heart muscle[7]—in other words, a cardiac "cramp"—which may be brought about by angiospasm or by partial occlusion of a coronary artery or one of its branches. Vasospasm occurs in about 10 per cent of patients suffering with angina and is induced by hypersensitive nervous mechanisms, by thyrotoxicosis, by ingestion of certain poisons, and by excessive inhalation of nicotine. Coronary thrombosis with anginoid pain is three times more prevalent in heavy smokers than in nonsmokers during middle age.[1] In 90 per cent of the cases diagnosed "angina pectoris," degenerative disease of the coronary arteries can be demonstrated.

A word of caution in regard to the close association between arteriosclerosis and hypertension. It is definitely accepted that arteriosclerosis does not produce hypertension. Hardening of the peripheral vessels alone is conducive to hypotension rather than high blood pressure since the elastic recoil of the arterial wall is greatly reduced by atheromatous infiltration of the intima. Arteriosclerosis may, therefore, exist for years without any rise of blood pressure. On the other hand, hypertension cannot be present for long without producing degenerative changes in the vascular tree. Hence it is difficult to say whether the high blood pressure caused the arteriosclerosis or whether the

unknown cause, or causes, of the hyperpiesis exerted a concomitant deleterious effect on or within the intima of the blood vessels.

Be that as it may, the actual cause of hypertension still remains a mystery. Numerous theories have been applied to the problem but all have been found wanting. The most rational hypothesis deals with the irritability of the arterioles causing vasospastic constriction which produces a proportional increase in peripheral resistance and this in turn necessitates an increase in hydrostatic force—that is, an elevation of the blood pressure—to cope with the augmented or heightened resistance in the peripheral circulation.

During the past decade considerable experimental work has been done on this problem, and it has been shown repeatedly that experimental hypertension can be produced by renal ischemia.[9-12] Furthermore, this rise in blood pressure (produced experimentally) is of humoral origin and arises as a result of the presence of an excessive amount of pressor substance in the circulation. This pressor substance is not actually produced in the ischemic kidney but rather is a combination of a precursor (renin) liberated by the damaged kidney and an activator (angiotonin) already in the blood.[13] Moreover, this pressor substance (hypertensin) acts directly on the arterioles to produce vasoconstriction. The clinical application of this recently acquired knowledge is, like prosperity, probably "just around the corner." In the meantime the clinical problem of hypertension—both the benign and the malignant type—continues to baffle the internist.

A confusion of tongues has arisen in the matter of nomenclature. The terms "malignant sclerosis," "malignant hypertension," and the "malignant phase of essential hypertension" all refer to the same syndrome. High blood pressure is not a disease entity but rather a symptom complex in which the hypertension is either primary (essential) or secondary to any one or any combination of a number of different diseases. This concept is not generally entertained but its validity is attested clinically by the fact that in the long run the *modus operandi* of every case of hyperpiesis is identical, no matter what its pathogenesis is or may have been. The malignant phase frequently develops after hypertension in the benign form has been present for a variable length of time, perhaps even unsuspected.

In a small percentage of patients hyperpiesis may apparently be malignant from its onset. This is termed the *de novo* form of the disease and may occur explosively in certain cases of primary hypertension or develop quite dramatically in patients who for many years have suffered from latent renal disease without any previous increase in their blood pressure.[14]

The onset of the malignant phase of hypertension (be it "primary" or "secondary") is characterized by severe headache, visual disturbances, vomiting, anorexia, cachexia, and exhaustion. These signs and symptoms in the presence of a systolic pressure bordering on 200 mm. Hg and a diastolic pressure in the neighborhood of 110 mm. Hg, or higher, predict a progressively rapid failure of the cardiac or renal functions. Patients with hypertension are all potential cardiacs or nephritics. Their clinical course is downhill (rapid in the essential or malignant type; slow in the benign or secondary form) and almost always terminates fatally in cardiac failure, or in apoplexy, or in uremia.

Patients suffering and dying from hypertension, or the effects thereof, can be segregated into several well-defined etiological and pathological groups, depending on the pathogenesis of their underlying disease, as follows:[14]

1. Primary or essential hypertension (cause, or causes, still in doubt).
2. Secondary hypertension due to—
   A. Renal disease:
      a. Glomerulonephritis.
      b. Pyelonephritis.
      c. Intercapillary glomerulosclerosis.
      d. Congenital unilateral hypoplasia.
      e. Obstruction of renal artery by atherosclerotic plaque.
      f. Multiple occlusions of small renal arteries.
      g. Renal infarct.
      h. Periarteritis nodosa of renal vessels.
      i. Polycystic kidneys.
   B. Chronic lead poisoning.
   C. Polycythemia vera; leucemia.
   D. Endocrine disease.
      a. Pituitary—basophilic adenoma.
      b. Adrenal—hypernephroma; paraganglionoma.
      c. Thyroid—thyrotoxicosis.
      d. Hyperemesis gravidarum.

Time and space do not permit further elaboration of the factors listed in the table. During life it is usually impossible to tell whether the patient is suffering from hypertension which is primary unto itself or is secondary to some unrecognized morbid lesion. Whatever the nature of the underlying pathological process, the prognosis is poor either in the long or the short run. Treatment is purely palliative except in those rare cases where the renal or glandular pathology is amenable to surgery. The results of sympathetic surgery in patients with the malignant form of hypertension have been uniformly disappointing.[15]

The term *cor pulmonale* refers to failure of the right ventricle as a result of increased pressure in the pulmonary circuit. This may occur in the acute form following a large pulmonary embolus but more frequently is a chronic affair as seen in emphysema, silicosis, stenosis of the pulmonary artery, and in extensive fibrotic tuberculosis, or in spontaneous pneumothorax (especially when bilateral). These conditions, when they do develop, usually appear during middle life.[2]

Cardiac disease caused by avitaminosis and dietary deficiencies, such as protein starvation, is rare in this country but is a possibility among the civil population during wartime. Myocardial failure due to the presence of a peripheral arteriovenous fistula—the traumatic variety should present no diagnostic difficulty—to tumors of the heart muscle and to deformities of the spine and thoracic cage is so rare that it will practically never enter the physical picture of the aviator approaching middle age.

There is one form of chronic myocardial insufficiency, however which deserves mention because its etiology is not clear, because it is frequently overlooked, and because its onset is insidious and its course progressive.

This is a nonvalvular cardiopathy characterized by congestive failure of unknown cause. Clinically, there is no evidence of hyperthyroidism or emphysema or avitaminosis or protein deficiency or blood dyscrasia. Neither are there any signs or symptoms of infection of the endocardium, myocardium, or pericardium. Nor can vascular degeneration nor hypertension be indicted—and yet the myocardium tires out during middle age, either early or late, and runs down like an alarm clock and stops.

At autopsy, the heart is found to be both dilated and hypertrophied, but the heart muscle otherwise appears normal to all intents and purposes. For lack of a better name such cases have been termed "chronic myocarditis," which is another misnomer since no inflammation of the myocardium can be found. The term "chronic myocardosis" has been suggested[16] to account for the dyspnea on exertion, the flatulence after meals, and the mild precordial pain (transient but recurrent) which warn of impending congestive failure. These symptoms, however, are quite frequently found in many cardiac syndromes and should not be assigned (or consigned) solely to chronic myocardosis. It may be more satisfactory to designate this symptom complex by the term "nonvalvular heart disease," or simply "chronic myocardial insufficiency."

Since heart disease is so prevalent and ubiquitous in middle life and since it is the most frequent cause of death and disability between the ages of 40 and 65 years, its prevention and early detection are of paramount importance. This is especially true for the profession of aviation, for while it is significant that anoxia causes a rise in blood pressure and pulse rate equivalent to that produced by mild exercise only, it has been realized more recently that the chronic stresses of flying eventually induce a generalized (and rapid) deterioration of the cardiovascular system.[17]

In most instances this premise applies, not only for the aviator but for the entire personnel of the Navy. In the past 20 years, the Bureau of Medicine and Surgery has recorded an alarming increase in coronary disease. The age incidence in these coronary deaths is lowering year by year and the morbidity is getting higher.[18] McIntire[18] states:

> Are we crowding our officers to a point where the cardiovascular system can no longer carry its load, or are we piling on so much responsibility that the nervous system cannot maintain its stability? . . . In the Navy a man must be physically fit to perform his duties at all times, in all places and under any condition. . . . It is the duty of the internist to find means of preventing disabilities, especially those due to degenerative disease.

While the call to duty in this respect is clear, the means of fulfilling this phase of our mission still remain obscure. This, in part, may be due to the fact that many of the methods and instrumentalities of modern cardiology lack precision. Some of the problems in this field of internal medicine yield only to empirical solution—or remain unsolved. Others are forced to rely for an answer almost entirely on the patient's history, which may be accurate and intelligent, yet incomplete; or it may be inaccurate and, therefore, worthless. Many of the signs and symptoms are transient; others notoriously absent when needed most to clarify the diagnosis. Even our present laboratory methods are far from infallible. Much must still be taken (and given) "on faith."

Pending that happy day when detection, recognition, prevention, treatment and after-care of the patient with degenerative cardiovascular disease shall reach a more rational (and simpler) plane, we must use our present scanty knowledge of the problem to the best possible advantage. Many time-honored procedures have proved their worth and have behind them the authority of regulations; other and newer concepts and diagnostic methods deserve consideration and fair trial.

Determination of the fitness of the cardiovascular system for continued military service is difficult because the examiner must rely chiefly on signs alone, and often these signs are of questionable significance. Tachycardia, systolic murmurs, slight elevation of blood pressure may attract the attention of the examining physician. Usually these findings are of no particular importance, yet their presence demands careful investigation. Is the tachycardia due to nervousness or to the presence of a "hidden" infection (notably tuberculosis)? Is the elevation of blood pressure relative or absolute? Is it a precursor of essential hypertension? Does poor response to exercise indicate an impending effort syndrome? How can these questions—and a host of others—be answered unequivocally?

In an attempt to arrive at a reliable evaluation of the cardiovascular system of the middle-aged flier one must first have a base line on which to "base" his judgment. This may date back to the general physical examination at the time of his enrollment or commission.[19] In addition to the routine Schneider test and examination of the ocular fundi, an electrocardiogram and teleroentgenogram of the heart would be desirable. The cold pressor test and "circulation time" may provide important information on the "tone" of the peripheral vascular tree. Annual fluoroscopic examination of the heart and aorta and routine electrocardiogram every year after the age of 40 may some day be included in the *Manual of the Medical Department.*

In regard to the strain of modern living and the extra stresses placed upon the heart and blood vessels by commercial and especially by military aviation, little can be offered other than education and advice concerning the value of rest and the art of relaxation while off duty. Excessive indulgence in alcohol, tobacco, and other forms of dissipation are no respecters of persons or occupations. Such habits probably hasten the onset and speed the progress of degenerative diseases of both the cardiovascular and nervous systems.

The personnel of our armed forces who are approaching middle age must learn to acknowledge and respect their physical and nervous limitations. To grow old gracefully and graciously still remains an art which is worthy of cultivation and patronage. By so doing, our officers and men will be enabled to render better service to our country and live longer, more useful, and happier lives.

RESPONSIBILITIES OF THE ARMY ROENTGENOLOGIST*

Lieut. Col. Alfred A. de Lorimier, M.C., U. S. Army

NOT infrequently the statement is made: "Roentgenology is roentgenology whether it be practiced in the Army or out of the Army." At first thought, this expression might seem to specify adequately the situation. In many respects it is true.

Scientific practice of roentgenology requires deliberative analyses of projected images on films or a fluoroscopic screen; a mental or recorded listing of tangible findings—the evidence described as "roentgen criteria"; an evaluation of such findings with respect to one or another pathologic entity; and finally, a correlation of the possibilities with consideration of the clinical aspects and laboratory studies. The roentgenologist must be recognized as a consultant. As such he must have a grasp of the entire field of medicine. He must exercise judgment just as required of a surgical consultant or any other type of medical adviser. These requirements are common both to the Army roentgenologist and to his confrere practicing this specialty in civil life.

There are a number of subspecialized qualifications frequently required of the roentgenologist practicing in civil life, which cannot be expected as demands upon the Army roentgenologist. For instance, rarely would the Army roentgenologist be concerned with pelvimetry, gynecologic roentgenology, or studies

*From the Department of Roentgenology, Army Medical School.

of infants and children. Moreover, in the theater of operations it can be expected that he will seldom have to deal with the treatment of malignancies—though this latter responsibility must be handled in certain general hospitals located in the Zone of the Interior.

These exemptions are more than offset by other requirements. The Army roentgenologist must possess an exceptional degree of ingenuity and the ability to command men and to coordinate very diplomatically the roentgenologic service; the ability to discern diagnostic criteria by way of roentgenoscopy without requiring film evidence; familiarity with foreign-body localization; special diagnostic acumen in the field of maxillofacial abnormalities; and a familiarity with requisitioning and handling of supplies.

Let us consider the magnitude of special qualifications such as these.

At a general hospital the roentgenologic service can be expected to be similar to that of any large civilian hospital. Similar services might be required at a station hospital.[1] However, at a fixed or a motorized evacuation hospital, at a surgical hospital, at a convalescent hospital, or on a hospital transport ship, in any of these locations, it can be expected that the roentgenologist will have to assemble his equipment; he will have to adjust it to one and another type of electrical supply, possibly disassemble it, move to a new location, and repeat this process over and over. In most instances, when trouble develops he will have to analyze the nature of the trouble and probably repair it himself. True enough, he will have assistance by way of enlisted technicians, but in most instances such assistants will be of unknown trust, and even though eventually trained they must be considered as transient. At best, he will be dealing with strangers much of the time. True enough, there will be repair centers, but these may be located at a considerable distance and available only after much delay. Therefore, the Army roentgenologist must develop himself to a standard of self-reliance, not only with respect to diagnostic problems but also in the handling of equipment.

In this connection it might be mentioned that the type of electrical currents available in one or another part of the world is very variable. The conventional current as found in the United States, 110 volts, 60 cycle, single phase, is not available widely throughout the rest of the world. In some locations, even here in the United States, 50 cycle current is used; in a few locations, it is a 30 cycle current. In our own Canal Zone it is 25 cycle. In most parts of the world, 50 cycle current, with a voltage of 200 to 260, is supplied the communities. Moreover, the most common type is three phase rather than single phase.

It has not appeared to be practical to provide means for altering the cycle such as might be available in one or another locality, since equipment required for such conversions would have to be very bulky and very heavy. However, it has been deemed practical to provide for adjustment of the voltage and the phase. This can be accomplished by use of a portable autotransformer. This item weighs approximately 80 pounds. It has a 70 foot line cable of a gauge satisfactory to handle relatively high wattage under conditions of voltages of the 200 to 260 range, and its design is such that it can be connected into the higher voltage line and deliver the lower voltage for which the portable field x-ray equipment and many other electrical devices have been designed. It may

be connected into two leads of a three-phase circuit so as to deliver single-phase current. Fortunately, the Army field equipment has been designed for operation on either 50 or 60 cycle current. Thus, with the aid of this autotransformer, our field x-ray equipment can function in most parts of the world. Where the cycle is less than 50, a special portable gasoline-electrical generator, having a capacity for 2,500 watts, may be used. Larger capacity mobile generators are

A.

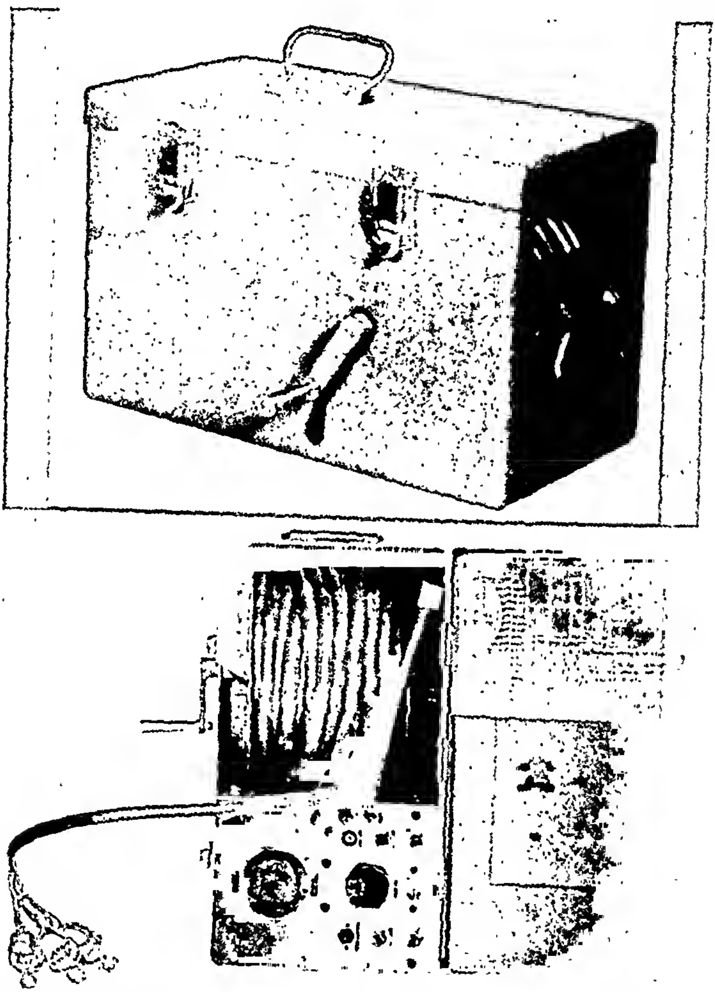

Fig. 1.—The portable autotransformer unit. *A*, Showing packing arrangement; *B*, top opened, showing 70 foot cable ready for fixation to open leads such as available in a distribution box. Note the meter for indicating the voltage applied to electrical apparatus connected into the secondary circuit of the autotransformer winding.

provided wherever needed. The requirements can be expected to differ in one and another location, and constantly it will be necessary for the roentgenologist to deliberate as to what adjustments are indicated. In these problems he cannot depend upon factory personnel or local electricians.

All field x-ray equipment has been designed on the basis of several limiting axiomatic principles.[2] All of it is portable. That which is to be used farther forward than "fixed types" of evacuation hospitals is packed in field chests.

Originally, it was intended that no one of these chests when packed should weigh more than 200 pounds. Because of various requirements including limitations on priority of materials, it has been necessary to deviate from this fixed policy. However, no one chest packed weighs more than 357 pounds (the gasoline-electrical generator). All the chests are balanced and so constructed that they can be carried by two to four men. Each item has been designed for multiplicity of adaptation. Single purpose application has been considered impractical. Besides providing that each item be usable for many purposes, the policy has been to provide usefulness for any type of hospital installation and to meet any type of situation.

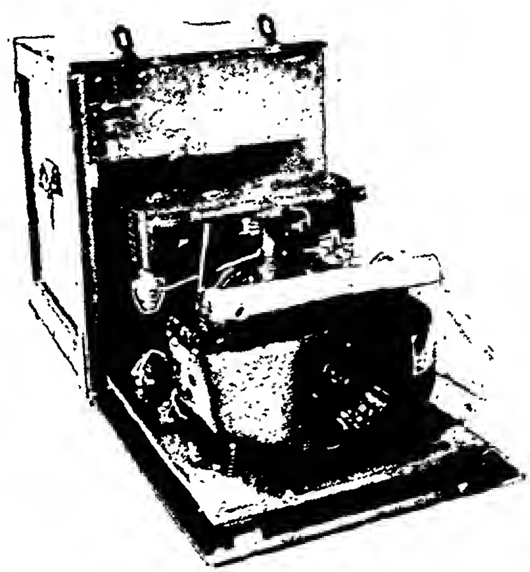

Fig. 2.—The portable gasoline electrical generator. Two gallons of gasoline provides for a supply of 2,500 watts continuously for approximately four hours.

For instance, the x-ray tent may be used for roentgenoscopy, with one arrangement of its inner curtain, or it may be used for film processing by merely changing the arrangement of its inner curtain and auxiliary drapes. Moreover, this tent may be erected by itself on the outside; it may be erected within another tent such as a ward or corridor tent, or it may be erected in any room or dugout. Under very windy conditions, it may be reinforced with the use of guy ropes. However, guy ropes and ground poles are not necessary. It is anticipated that in many instances dugouts or cellars will be utilized. The tent as well as all the other equipment can be adjusted quickly to such a situation. In fact, with forceful supervision and with very little training of three or four technicians, it is possible to move into a new location and to set up the entire equipment as needed for roentgenoscopy and to be ready to function within fifteen minutes after the time of arrival. This same equipment might be mounted onto closed trucks, thereby being made available for usage at a moment's notice.

The x-ray table unit, together with the x-ray machine unit and its chassis, has been designed for a nine-way adaptation. They may be adapted for horizontal roentgenoscopy; for a rapid roentgenoscopic method of foreign-body localization; for sitting roentgenoscopy; standing roentgenoscopy; horizontal roentgenography, with the tube above the table; horizontal roentgenography, with focal film distances as great as 6 feet, the patient being positioned on a litter at the floor

A.

B.

Fig. 3.—The darkroom tent: *A*, As erected for roentgenoscopy—note the forward position of the inner curtain. level; vertical roentgenography, using similar long focal film distances; bedside roentgenography (utilizing a mobile arrangement of the x-ray machine unit); and finally, this equipment may be used for roentgenotherapy for conditions requiring a quality of x-radiation, such as produced with a kilovoltage of 100—infections (including gas gangrene) and dermatoses.

All these applications must be understood, and the roentgenologist must be capable of quickly adjusting not only to new conditions but also to any of a

variety of demands with the minimum of equipment. In connection with foreign-body localizations, it should be emphasized that another item has been developed, a "biplane marker and reorientating device." This item is of a design such as to provide for its being adapted to the roentgenoscopic screen. It is designed to serve for spotting onto the skin of the patient, the location of the foreign body with respect to a plane at right angles to the plane concerned with the roentgenoscopic localization. This *second* spotting and localization are accomplished without any x-radiation exposure of the patient, and without the use of x-radiation at all. It provides for spotting of the position of the foreign body just as might be accomplished with the use of biplane roentgenoscopy. Yet, the shortcomings of biplane roentgenoscopy: the bulk of a second tube and second roentgenoscopic screen or the time delay concerned with shifting a single tube and screen from the first plane to one at right angles to it; difficulties of visualization of a small foreign body through great thicknesses and densities concerned with lateral planes, and the increased x-radiation exposures with respect to both the patient and the roentgenoscopist such as required for viewing in the two planes—all of these shortcomings are overcome with use of the biplane marker.

This "spotting" in the two planes serves for more definite guidance to the surgeon. It can be anticipated that the patient may be lying in one position during roentgenoscopy, whereas he might be rotated to a different position for the surgical approach. The surgeon may not appreciate these variations of relationship and he may, therefore, approach the foreign body along a plane at variance with the plane concerned with the alignment of the foreign body to the spotting on the skin surface. Perhaps, due to anatomic limitations, the approach may have to be from an altogether different plane relationship than either of two planes so far considered. In such cases, biplane marking itself should indicate the true relations and guide the approach.

In some instances, it can be expected that the surgeon must be assisted even further. It may be necessary to re-establish more thoroughly the relations on the operating table, as they pertained during the localization procedure. For this, the two spottings on the skin surface already mentioned may be used in connection with the re-orientating device to indicate very definitely relations for proper positioning. This device contains three adjustable probe directors. They can be detached for sterilization purposes and if needed they can be repositioned onto their respective supports and used right in the operative field under conditions of surgical asepsis. One probe may be positioned for indicating the plane with respect to the spotting as accomplished with the roentgenoscopic procedure; a second one may be positioned for indicating the plane concerned with the spotting as accomplished with the biplane marker; the third probe may be positioned for directing the plane of any operative approach that the surgeon might have selected. Thus localization may be accomplished with respect to *any* plane. The roentgenologist is charged not only with the "spotting" of the foreign bodies and calculating depth values with respect to them, but he must actually coordinate with the surgeon in accomplishing their removal.

These procedures do not require the use of films. All of them can be accomplished within time limits of a few minutes. Actual energization of the x-ray equipment and radiation exposure should not exceed fifteen to forty-five seconds.

depending upon the experience of the roentgenoscopist. For precision, though, it is necessary that one be alert to conditions which might result in errors and that he be understanding of the means of correcting such. With each disassemblage and with each assemblage of the equipment following packing and transportation, at least minor damage, such as stripping of threads, perhaps bowing of the localization scale or bending of the depth marker, warping of the roentgenoscopic screen, etc., can be expected to occur. Unless the roentgenologist is constantly alert, such defects will lead to not one or a few mistakes but to a continuous repetition of mistakes.

A small depth phantom has been provided, this being supplied for the purpose of preliminary checking of the accuracy of the localization. Moreover, an adjustment means is incorporated into the supporting arm of the roentgenoscopic screen to correct for variations in focal-spot-roentgenoscopic screen distance due to abnormal positions of the focal spot itself. Adjustment of the reading level concerned with the depth scale has also been provided. This latter provides for cancellation of errors which would otherwise occur due to warpage or corrugation of the roentgenoscopic screen or to tangential viewing by one or another roentgenoscopist with resultant parallax. In short, provisions have been made to compensate for those variables which are beyond the scope of control by the manufacturers. These provisions theoretically mean absolute accuracy. Nevertheless, the degree of accuracy is dependent upon knowledge of the fundamentals, together with the integrity and scruple of the roentgenoscopist.

This general procedure of foreign body localization has been considered adequate to handle foreign bodies in all locations other than in the eye. For localization of intraocular foreign bodies, the "Sweet method," such as used in World War I, still appears to be the most practical. This method requires the use of film. Therefore, such localizations cannot be expected in the very forward zone. They will be accomplished in the more fixed types of evacuation hospitals and general hospitals, where films and processing equipment are available. This particular method is well known to roentgenologists in civil life. Detailed description of it, as well as explanation of the roentgenoscopic procedure, is published in the *Technical Manual 8-275*[3] and elsewhere.[4]

In the very forward installations, such as the surgical hospital, the roentgenologist is the sole diagnostician. In the motorized evacuation hospital, he is one of four diagnosticians. Internists and collaborative consultants are included with installations located farther to the rear. However, due to the requirement of having to arrive at quick decisions and, of having to handle so many hundred cases each day, the roentgenologist may be rated as one of the most useful consultants. He must be capable scientifically, and he must also be very ethical in dealing with his confreres. He must be a coordinator. The attitude of *service* must dominate his actions.

His coordinating spirit must not be limited to his own relations with respect to his doctor confreres. He must be able to command men. In certain locations, he may have only three technical assistants; in others, as many as ten or twelve. Under conditions of warfare, the doctor, the officer, and the enlisted personnel must work shoulder to shoulder. Nevertheless, the enlisted personnel must not be leaned upon too strongly. The roentgenologist must conservatively control the group.

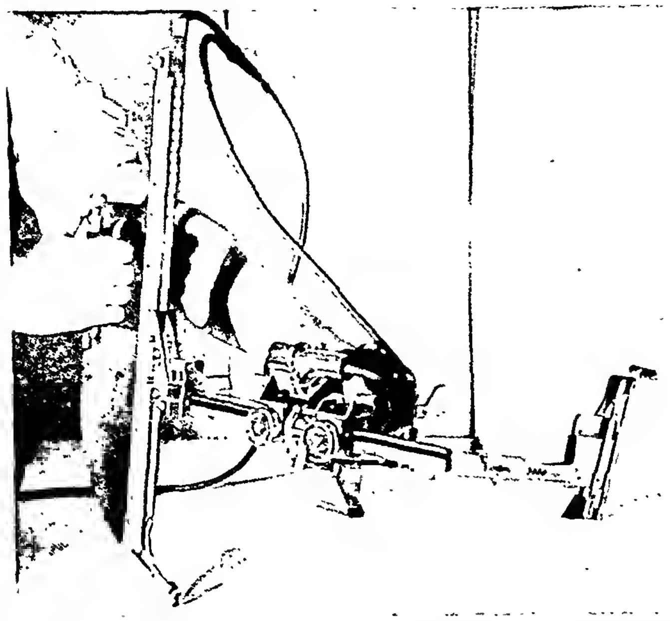

Fig. 5.—The biplane marker. The operator is about to fix this device to the roentgenoscopic screen. Marking in the second plane is accomplished without any x-radiation exposure. Note the pilot lights and cables, provided for manipulating this apparatus without losing accommodation of the darkroom.

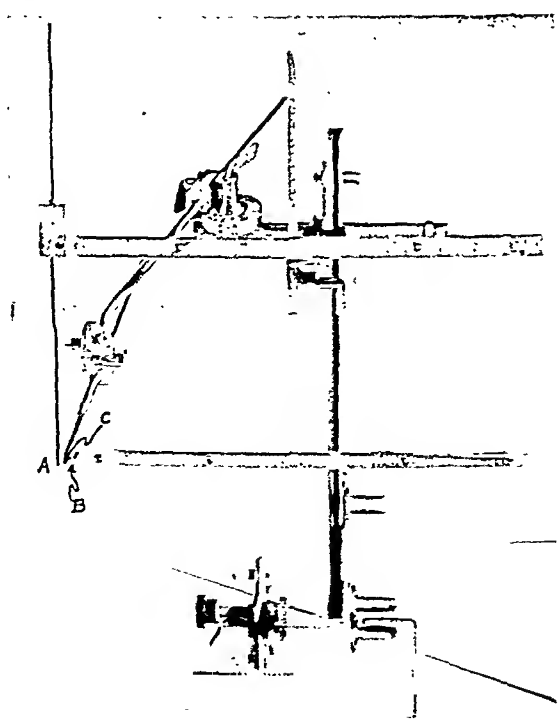

Fig. 6.—The reorientating device. Note the three pointers: *A*, Concerned with the spotting as accomplished with the roentgenoscopic procedure; *B*, that concerned with the spotting as accomplished with the biplane marker; and *C*, the indicator concerned with any selected surgical approach.

As mentioned in the beginning, the diagnostic responsibilities are almost of as great a scope as those with which the civilian roentgenologist has to deal. There will be need for roentgenoscopy of the extremities, with interest as to soft tissue wounds—possibly with interest as to gas bacillus infections. There will be problems relative to fractures; these under conditions of fixation with splints or plaster casts. There will be problems pertaining to wounds in the abdomen and thorax, and there will be problems concerned with a gamut of pathologic conditions besides those of trauma for any of these parts. True enough, similar diagnostic problems are experienced by a well-practiced roentgenologist in civil life. However, in Army roentgenology it can be expected that roentgenoscopy will have to be emphasized over roentgenography. Resort to films requires more time than can be expected to be allowable during stress of activities such as are to be expected in the theater of operations. The roentgenologist must have developed a very keenly discerning eye. Of all phases of roentgenology, it would seem that the field of maxillofacial abnormalities must prompt his particular study and proficiency. Tank and air service casualties, as well as those concerned with ordinary motor transportation, must be expected. There are so many contours concerned with the facial bones and the cranium itself that distinct visualization of any one portion of the head is a difficult task under any conditions. The Army roentgenologist must be thoroughly understanding of all of these contours and of the several positionings concerned with most adequately visualizing one or another portion. He must have a knowledge of anatomic weak sites. He must be equipped with a knowledge of the physiology concerned with the various muscle actions which might serve to alter relations in case of fracture in one or another location. He must be able to discern roentgenoscopically these conditions which are admittedly difficult of diagnosis even with the assistance of films.

The Army roentgenologist must be acquainted with the normal procedures which pertain to procurement of x-ray equipment and materials and, thereafter, their proper handling. With most civilian institutional connections, the roentgenologist may sense merely a moral responsibility for protection of the equipment in his department. Unless he has actually purchased it, paying from his own resources, it is very natural that he should consider it the property of the institution, and it is very unlikely that unserviceability of any part of the apparatus would result in any financial loss to the doctor. Not so in the case of the Army roentgenologist! Though the equipment belongs to the United States Army, it is necessary that it be entrusted to a responsible person, an officer. In case proper accounting cannot be made for unserviceabilities or losses, a depreciated value of the equipment may be deducted from his pay.

Except during periods of actual combat, the Army roentgenologist must anticipate equipment and property needs. He must initiate the requisitioning of these. In this regard, he must realize the necessity of confining his wants, as far as possible, to a list of items considered most practical by our Supply Department. These items are contained in the supply catalog, which is ordinarily in the possession of the medical supply officer. The listing is of "standard items." A supply of such items is usually maintained at a near-by depot. Standard items

are listed according to classes. There are nine such classes. The classification has been made on the basis of general purposes or the type of the commodity.

The roentgenologist is mainly concerned with Class 6 or Class 9, insofar as x-ray equipments might be needed. Class 6 contains a listing of standard x-ray equipment such as might be needed for general hospitals and peacetime installations. Class 9 contains a similar listing of equipment which might be needed for installations such as the mobile surgical hospital or the evacuation hospital; installations operating in the theater of operations. Processing chemicals, such as would be needed for roentgenography, are contained in Class 1. For police and maintenance of a clinic, such as might be concerned with a fixed evacuation hospital or a general hospital, including furniture, cleaning items, stationery, miscellaneous office equipment and linens, are all listed under Class 7.

Nonstandard items are always more difficult to obtain, though where especially needed they can usually be obtained. They are not described in the supply catalog. Spare parts and replacements may be listed, though in many instances they, too, must be purchased as nonstandard items.

Items are carried as expendable or as nonexpendable. Furthermore, they may be identified as deteriorating or nondeteriorating. The roentgenologist must appreciate these characteristics and supervise the care and handling of this equipment as scrupulously as possible. In order to provide for efficiency in handling purchases and unit requisitions, it is necessary for him to understand the problems of the medical supply officer and to anticipate his needs so as to provide for including his requisitions as far as possible at prearranged times.

Except for expendable supplies, a central record is kept of all items issued. The roentgenologist is given a copy of the list for which he is responsible. It is important to inventory the property records and to identify each item when packing for a change of location, when reassembling and otherwise, at least once each month.

Illegal sales have been made of all types of Government property, but in particular, "consumption" of x-ray films must be watched. It is advisable that films be stored within a locked cabinet or a locked room, and that the keys to such be held by one person in the department. A tabulated record of quantities received versus quantities removed from this storage should be posted within this cabinet or room. This record should include the date, the film size, and the quantity concerned with each increment and with each issue, together with the initials of the person receiving them. This record need not be elaborate but it should be complete.

In larger x-ray clinics, besides keeping a record of all films received and all films issued, it is advisable that each roentgenographic technician and also those concerned with processing in the darkroom be required to report the total number of films used or handled each day or each week, as well as the number of films wasted. This system provides for checking the reports of the individual roentgenographic technicians with the summation report by the technician or technicians in the processing room, and both reports with the records contained in the film cabinet or film storage room. Usually, the psychologic effect of such a system will counteract any inclination toward "bootlegging" of x-ray films.

There is a similar temptation for certain people to enter into illegal sales of intensifying screens. These screens are very expensive. They can easily be removed from cassettes, and secondhand screens or blank cardboards may be used for substitutions. Because of such practices, it is advisable to identify each screen with the words: "Property of the United States Government." This description might be written with indelible ink along a margin of the screen whereby the wording will not be reproduced onto useful portions of the roentgenogram. If these captionings are accomplished in the handwriting of the radiologist, there will be provided a definite challenge in case roentgenograms are found in the department which do not bear his handwriting, even though it be evident that such roentgenograms were obtained with the use of cassettes.

These responsibilities pertain, in a general way, to all Army roentgenologists. Whereas one day he may be assigned to a task requiring knowledge in one phase of roentgenology, at another time he can expect a different or more comprehensive assignment. Anticipation of duty in the field of combat should be in the minds of all. In a previous paper[2] the responsibilities of the roentgenologist were considered in terms of the home communities versus the anticipated duties in the theater of operations. Preliminary work has been essentially concerned with chest examinations.[5] This phase, too, is subspecialized to the extent of having to deal with miniature films and with hundreds of studies each day—mass survey studies—and being guided by regulations with respect to acceptable versus unacceptable findings. Most of this work has been concerned with chest roentgenology—known to qualified roentgenologists and phthisiologists. The plan of this phase has been so well crystallized that detailed description of it would seem to be unimportant at this time. It must be realized, however, that these activities are continuing, and they must be expected again on a very large scale at a time of demobilization following completion of the gigantic task in which we are now involved.

SUMMARY

In general, it is realized that "roentgenology is roentgenology whether it be practiced in the Army or out of the Army." The Army roentgenologist is spared certain responsibilities, such as those concerned with obstetrics, gynecology, and to a large extent, those concerned with children's diseases and radiation therapy of malignancies. However, these exemptions are more than compensated by a number of requirements such as exceptional ingenuity, an ability to command men, and very diplomatically coordinate the roentgenologic service; particular acuity of diagnostic ability by way of roentgenoscopy without requiring film studies; familiarity with foreign-body localizations and familiarity with requisitioning and handling of equipment and supplies.

EFFECTS OF MODERN WARFARE ON CIVIL POPULATION

Experience of Great Britain*

D. Denny-Brown, M.B., F.R.C.P.

To begin with I shall outline some general aspects of air bombing and procedures taken by the civil authorities, such as evacuation and provision of shelters, because these affect the type and kind of nervous casualties from air raids. Indeed, prophylaxis is more important than treatment.

It was anticipated that any densely populated area which was subjected to military bombing would be the scene of mass panic and mass hysterical phenomena, as well as mass destruction. Yet, bombing of civilian population has failed to produce any sort of mass panic or nervous manifestations. That was first evident in Barcelona during the Spanish War, where the population settled down to a daily routine of their occupations for months of severe bombing. We have very little direct information of the effects in China or Warsaw or in Rotterdam, but there is certainly no report of such mass nervous reaction. There has been nothing of the sort in London or Coventry or any of the other British cities that have been intensely bombed. I think the chief reason is that the population is prepared by earlier, milder experience. If the Luftwaffe had taken the opportunity to bomb London on the very first day after war was declared and had caught a densely populated area at a time when nervous tension was at its height, the tale might have been different. But, in actual fact, there was sufficient warning, it was always obvious that things were getting worse, and nearly always people have experienced bombs at a distance before they have experience of bombs close by. Possibly most of those who feel they cannot go on with it manage to get away somewhere where bombing is not so intense.

The destructive effect of a bomb dropped from the air is extraordinarily limited. In the towns that have been bombed, you will see a house missing here, a shop missing there, or a large hole in the street. Houses on either side are battered by flying masonry but are not blown down. Within a radius of twenty or thirty yards there is utter destruction, and beyond that things are left standing. Within quite a much wider radius all glass, windowpanes, and often door frames, are broken by the blast of the explosion. Under those circumstances it is, therefore, fairly obvious that though a shelter of any sort has to be very strongly built, and if possible, to be deeply built in order to escape the effects of a direct hit, there are relatively very few chances of such a hit. A deep underground shelter is about the only place that is safe from a direct hit, but underground shelters are very expensive to build. It is impossible to build sufficient deep shelters for the whole population of a city. It would virtually be another city under the ground. Further, even deep shelters have

*Lecture XXIII, reprinted from *Collected Lectures*, the Metropolitan State Hospital, Waltham, Mass., 1942.

disadvantages in that occasionally an explosion near by will fracture deep water and gas conduits, and so bring danger of drowning or poisoning to the occupants. Many nervous people will literally spend all their time in deep shelters if they can. They are better evacuated from the area. It is more satisfactory to have people scattered as much as possible rather than have them all together in one place. The ordinary person is accordingly encouraged to take shelter in basements under or near his own home or near his place of work rather than to seek some large public shelter. A percentage of bombs dropped indiscriminately fall not in buildings but in streets, yards, and other spaces, even in a city. Any modern steel-frame building offers fair protection. Bombing of towns in broad daylight in the face of an air force that has any real strength has proved to be too expensive for the air force concerned, so that it is mainly a nocturnal experience. Shelters should be warmed, should be provided with some sort of sleeping accommodations, bunks, and they should be provided with adequate sanitation, and, if possible, with some first-aid arrangements.

While many people will take shelter, there is much to be done on the surface. The most efficient weapon of an air force seeking to destroy industry or communications is the incendiary bomb. Thousands of these bombs can be dropped rapidly in a small area, and twenty minutes later, when a few fires have started, another group of bombers can drop more high explosives and more incendiaries. If the incendiaries are extinguished, the damage is minimized and the bombers do not see their targets. It is essential to have large numbers of the population on the watch for them, on every roof with sand and spray pump to extinguish them rapidly wherever they fall. For this reason, in every area likely to be bombed the population has much to do besides take shelter. Clerks, bus drivers, professional men and women, all except children, have to take turns in fire-watching homes, industries, offices. Thus people are as widely dispersed as possible in any underground shelter or basement, and many others are fire-watching. In addition there is the ordinary force of civil air-raid wardens, ambulance and first-aid posts, and accessory fire tenders manned by part-time and full-time personnel, as well as the regular municipal hospital and fire services. One-third of the population is engaged in some form of "air-raid defense." In such a scattered and occupied population the casualty rate in one heavy night bombing in a place of 100,000 population would be approximately 250 to 500 people injured in the raid, depending upon its intensity.

A number of problems arise from this sort of organization. An air raid is a terrifying happening, but the effects are minimized by good organization. Hospital services are scattered as much as possible. Emergency light and other services are prepared. The sorting of casualties is arranged so that someone responsible sees every casualty on arrival and immediately attaches an appropriate label. The most important category is shock, because many patients with multiple injuries are dug out and are found to be severely shocked on arrival to the hospital. All patients referred with purely nervous symptoms are segregated. The responsibility on those who segregate the patient is high, for they should be able to distinguish shock and hysteria, be immediately able

to direct the excitable patient or the patient who is simply mute, or the patient who is in a state of stupor, to a place where he can be dealt with separately. It must not be forgotten that occasionally patients who are in a state of stupor may get very cold and shocked, even though they actually may not suffer any particular bodily injury. For many patients a hot drink and a sedative are sufficient. The most useful drugs are bromide and chloral, a mixture of 30 grains of bromide with 20 grains of chloral, but occasionally morphine is used. From 50 to 75 per cent of the patients suffering from nervous conditions during air raids will be ready to go home after having hot coffee and a sedative and after having been allowed to rest or sleep until morning. The remainder are admitted the next day to a subsidiary hospital outside the town. A large building in the country, a big school, or more often a mental hospital, part of which has been evacuated so that three of five or six wings would be used for the reception of casualties, is used.

With this sort of scheme, the original large city hospital is arranged to accommodate perhaps only 150 patients as a casualty hospital. In between air raids the normal population still attends out-patient clinics of the original hospital, and patients requiring hospital admission are admitted not to the parent hospital but to one of the rural subsidiaries. The arrangements are always such that the subsidiary keeps about three-quarters of the beds prepared for casualties. This system has never at any time been overstrained. In fact, there are many critics who say it is too elaborate. However, it is very possible that air raids will be more frightful still, since so far all belligerents have been spared the horrors of gas warfare.

The general procedure with nervous and psychiatric casualties is to move all who have not recovered in four to six weeks to special hospitals for such cases. It has been found necessary in London to have only two hospitals devoted entirely to nervous disorders, and neither of these has ever been completely filled. It has never happened that such a large number of strictly nervous casualties has occurred in any one place that they should have to be admitted direct to any particular hospital for nervous disorders. There were at the beginning at least three other special hospitals set up for nervous casualties, but these were long since disbanded. Most nervous casualties recover rapidly. By far the most common type of nervous casualty is stupor or hysterical fugue. When bombing goes on night after night for two weeks or more, a number of people break down, but usually before this condition occurs they are persuaded to go to the country for a one or two night rest, and are aided by some organization set up for the purpose. Everyone feels it is his or her duty to stay, so that some intelligent supervision is necessary to make the best of such arrangements. What most people need very badly is sleep, and a good organization will arrange beforehand to send everybody in rotation away from the city for two days with friends or billets in the country. They sleep solidly for the first twenty-four hours, then relax for another day and are ready to go back again.

Transient conditions of exhaustion, with anxiety symptoms and depression of various degrees, and fugues are extremely common. There are different kinds of dissociated state. In some the condition is very superficial, and the amnesia is recalled with only slight assistance. In others it is deeper and some

assistance by suggestion or hypnosis is required. I think it is essential to recover the amnesia in most cases. In still other cases the dissociated state or fugue is only one aspect of what is very much deeper emotional depression, and even if you succeed in clearing the fugue, a depressed state with retardation, often some depersonalization, remains. The illness has then a certain momentum which will take several weeks, perhaps five or six months, to overcome. Such patients must be dealt with in special hospitals with such treatments as continuous narcosis, which in my experience has been most satisfactory, except that it does require very skillful nursing and personnel. Convulsive therapy is little used for such cases.

It is difficult to get any statistics, for psychiatric casualties are mixed up with all others at the start, and are moved so rapidly and so far. No doubt official figures will be available in time. But I can say that from very large cities, such as London, the scale of persistent disability is very little more than the rate of peacetime nervous illness (their population being now much lower through evacuation of women, children, and some industries to the country).

Those dealing with psychiatric casualties have found, just as those dealing with psychiatric conditions in the Army and other services have found, that it is the person who has had constitutional history and previous bad personal history who is liable to break down. If you select those patients who have not recovered after six weeks, the proportion of them who have either bad family history, or history of previous breakdown, or both, is very high indeed, sometimes over 90 per cent. So it is the peacetime psychoneurotics that turn up under war conditions with breakdowns. People can adapt themselves to all conditions. If breakdown does occur, it has a natural tendency to recovery. Certainly I am sure young children are affected very much less than adults. Children up to the age of 3 or 4 do not appear to realize what is going on. I have seen nervous children between the ages of 6 and 12 years with tics, enuresis, troubled sleep, screaming attacks, tantrums, etc., if they are upset by an air raid, but most of them settle down very quickly. A very small percentage of children suffer from persistent nervous conditions, and these are usually constitutionally nervous children. In some all this disturbance of ordinary life is a help to psychoneurosis. Some chronic neurotics of peacetime now drive ambulances or fire tenders and complain no longer of their nervous symptoms. The more simple anxiety state, if there is something really worth while to get on with, can be really benefited by all this organization and feeling of urgency. If a breakdown occurs, it will, of course, be more severe. But the herd instinct can have beneficial effects, and the rejuvenation of the chronic psychoneurotic is one of them.

Apart from the direct effects of the air raid, there are other problems related to evacuation. It is important in densely populated areas to try to get everybody who is not occupied in essential work out to some other place, to move industry, and women and children from the densely populated areas to country areas where bombing is either not likely or not dangerous. Communications are not always good, and the wife with her children in the country soon gets worried as to what has happened to her husband in town. In England all evacuation is purely voluntary. The government pays the expenses of moving the family to the country, but, of course, the wage earner still has to pay the rent for his

apartment or house in town, and he has to contribute to the upkeep of the family in the country. There is a much greater stress on the family budget. Such anxieties can in part be dealt with by a good social service organization. A framework of experienced social service workers can function very efficiently if sufficient voluntary help is available from women's societies. A small bureau is established in every town and village for evacuated people, managed usually by one paid secretary and a number of volunteer workers, and is called the Citizens' Advice Bureau. Advice is given on all problems, communication with relatives, notification of casualties, procedure in relation to paying rents and claims for damages. Such an organization is an excellent prophylactic for psychoneurosis.

THE CHEMOTHERAPY OF BACILLARY DYSENTERY*

FURTHER OBSERVATIONS ON SULFAGUANIDINE

COMMANDER GEORGE M. LYON, M.C., U. S. N. R.

THE use of sulfaguanidine in the treatment of acute bacillary dysentery has been described in a report[1] based on the study of a small series of patients having the disease in a severe or moderately severe form. In this study alternate patients were treated with the chemical while others, as controls, were not. Since that time sulfaguanidine, the guanidine analogue of sulfapyridine, has had extensive practical application in the management of patients with "bloody flux" in the offices, homes, and hospitals of an area wherein bacillary dysentery is an important disease. An unusual opportunity for this study was presented by the occurrence, during this time, of what was probably, in the counties concerned, the highest incidence of the disease since 1926. More than 300 patients with "bloody flux" were treated with sulfaguanidine. Their records permit an appraisal of the effectiveness, and the suitability of this chemical agent for general practice in the treatment of acute bacillary dysentery, not only in the hospital, but of perhaps even more practical importance, in the offices and homes as well. A more detailed analysis of these records has already been presented.[2-4]

With few exceptions the method of administration employed was that originally recommended by Marshall[5] and employed in the previous clinical study.[1] The initial dose was 0.1 gram per kilogram of body weight, while the maintenance dose was 0.05 gram per kilogram of body weight administered orally every 4 hours until the stools were less than 5 in 24 hours, and then 0.05 grams per kilogram of body weight every 8 hours for 48 to 72 hours. That an adequate urinary output should be maintained, had been stressed repeatedly and in general was well observed. Particular attention was paid to the detection of any untoward effects which might result from the administration of the relatively new chemical.

*Received for publication, October 30, 1941.
Reprinted from the United States Naval Medical Bulletin 40: 601 (July), 1942.

From this experience certain impressions have been gained in addition to which there are some more definite conclusions which may be drawn, and it is, therefore, possible now to present further recommendations in regard to the clinical use of the drug.

Sulfaguanidine proved to be an effective therapeutic agent in the treatment of acute bacillary dysentery. When used in the manner described, and when treatment was begun during the first 5 days of illness, recovery usually occurred in 2 to 5 days. In the majority of instances, 5 days of chemotherapy was all that was required. When so used sulfaguanidine was entirely free from toxic effects. This freedom of dangers from toxic effects is in striking contrast to that of the other sulfonamide compounds, one of which, sulfathiazole, is described as being quite as effective as sulfaguanidine in the treatment of acute bacillary dysentery and which indeed may be more effective than sulfaguanidine in the treatment of the diarrheas resulting from parenteral infections.[6, 7]

As previously stated, when chemotherapy was begun within 5 days of the onset of fever or diarrhea, and when employed in the manner described, recovery almost invariably followed in 2 to 5 days. When not employed until later in the disease, results were frequently amazingly good, but failures were encountered somewhat more frequently. When treatment with the drug was begun after the fifth day and before the eleventh day, results, as a rule, were better than when begun after the eleventh day, but not as good as during the first 5 days. The importance of early treatment cannot be overemphasized.

When there was blood and pus in the stools and when there was fever present, even though the treatments were not begun early in the disease, results were nearly always as satisfactory as in the patients treated earlier. When, however, the dysentery bacilli had disappeared, and when there was no blood or pus in the stools; when the stage of bacterial activity was past and the stool was of the green watery type (so characteristic of the frequently encountered "post-infection" intestinal indigestion), sulfaguanidine had the least beneficial effects. This is to be expected, however, in view of the underlying pathology.

It is an outstanding characteristic of acute bacillary dysentery, although one frequently overlooked, that with remarkable frequency the stage of active bacterial infection is followed by an impaired ability on the part of the intestinal tract to digest and to assimilate food. It is generally accepted that this occurs as a result of the damage produced within the gastrointestinal tract by the dysentery bacilli, or their toxins. This form of "post-infection" intestinal indigestion was formerly very common among infants and young children, and is not infrequent today in those dysentery patients not receiving chemotherapy. Although less common in adults, this sequela is not at all an infrequent one. Since this condition results from damage done to the intestinal tract by the bacilli themselves, or by toxins produced by them, and since the bacilli by this time have usually left the intestinal tract, or have been supplanted by secondary invaders, one cannot expect sulfaguanidine to be such an effective agent in clearing up this diarrheal state. In actual practice it did not do so.

Sulfathiazole is said to be effective in those cases where the continued diarrhea is the result of secondary invaders, with or without deep ulceration. On

theoretical grounds there is indeed much to recommend it, or sulfadiazine, in such instances, and either may be more effective than sulfaguanidine. Fortunately, such conditions are not commonly encountered and practically never occur if chemotherapy is instituted early in the infection. Occasional cases of diarrhea were encountered which appeared to be simple watery diarrhea, without significant bacterial infection, without blood and pus in the stools, and which, despite adequate chemotherapy, did not yield to either sulfaguanidine or sulfathiazole. In such cases the diarrhea may possibly have been due to:

1. A previously undetected acute bacillary dysentery with the subseqnent development of the "post-infection" intestinal indigestion already described.
2. A parenteral infection not discovered.
3. A diarrhea due to a local or systemic virus infection.

In general, the best results with sulfaguanidine were obtained in those patients treated earliest after onset, who were most ill, and who had blood and pus in their diarrheal stools at the time chemotherapy was begun. It was least effective in those in whom treatment was not started until after the acute bacterial invasion was over, when the stools were simply green, watery, and without blood, pus, or dysentery bacilli.

Sulfaguanidine appears to be equally effective against all of the various strains of dysentery bacilli. Paradoxical as it may seem, it has appeared to have its most striking effect in the treatment of the toxic Flexner and Shiga strains. Two instances of Shiga were added and the results were the same as with Flexner. This has since been amply confirmed by Hardy and others. There is some limited evidence to suggest it was somewhat less effective against the clinically less toxic Sonne strain, one which so frequently gives rise to mild afebrile diarrhea without blood in the stools and often with little pus.

Most of the toxic effects which have been observed in the use of the other sulfonamides have also occurred following the use of sulfaguanidine. Such have, however, occurred almost invariably when the drug had been given in doses larger than recommended by Marshall and doses that were larger than those employed in the present study, and when, likewise, due regard was *not* paid to the importance of the frequency and the character of the stools, and to the relationship this has to the concentration of the drug in the intestinal tract when the stools are infrequent. Such toxic effects can be avoided almost entirely by employing the drug as recommended originally by Marshall, provided there is meanwhile an adequate urinary output, which definitely enhances the likelihood of there being no toxic effects. An adequate urinary output is always a desideratum in the treatment of acute bacillary dysentery. The fact that treatment is usually terminated in 5 to 7 days is an added safeguard against toxic effects. Toxic effects may have been encountered somewhat more frequently in adults than in infants or young children where they they were almost entirely missing.

Although sulfaguanidine was least effective after the first 5 to 10 days of illness, and after the blood and pus in the stools had given way to the plain watery stool which contained no dysentery bacilli, there is sufficient evidence at hand to indicate the desirability for the use of sulfaguanidine in all suspected cases of bacillary dysentery, "flux," or "infectious diarrhea" with

fever. It should be given for 5 to 7 days and thereafter if recovery has not occurred it may be best to give sulfathiazole, or still better, perhaps sulfadiazine, for another 5 to 7 days. In the meantime, strict regard must be paid to the urinary output, for with all of the sulfonamide compounds there is a strict relationship between adequate urinary output and freedom from toxicity. This is particularly to be remembered in the use of sulfathiazole and sulfadiazine.

Where there are obvious or suspected infections outside the gastrointestinal tract, it may be desirable, at the onset, to use sulfathiazole, or sulfadiazine, in the place of sulfaguanidine. While in such instances this practice may perhaps be more effective, in the experience described, it was never necessary to resort to it in the early stages of the acute infection. Also it presented no strikingly favorable results in the treatment of those cases with such complications observed 10 or more days after the onset of diarrhea.

Although potentially carrying a greater risk of toxicity, both sulfathiazole and sulfadiazine have been shown to be effective in the acute stages of bacillary dysentery. Because of their greater tendency to produce toxic effects, and because of the greater care with which they must be given, it would seem that they should be the drugs of secondary choice in the treatment of acute bacillary dysentery in the early stages. In the later stages, or in the state of "post-infection" intestinal indigestion, their use may be more strongly indicated. For use in the home, office, or dispensary they are definitely not so safe as sulfaguanidine, and should not be employed as sulfaguanidine may be. One of the most satisfactory features of sulfaguanidine is the large margin of safety permitted in this respect without sacrificing therapeutic efficacy. It is necessary, frequently, to treat cases of acute bacillary dysentery without the benefit of hospitalization. For them sulfaguanidine is distinctly the drug of choice. Experience has proved that good results have followed this practice.

Excepting newborn, no deaths occurred among the patients treated with sulfaguanidine, provided treatment was begun during the first 5 days of illness (diarrhea and fever) and such cases did not have other important infection outside the intestinal tract. Parenteral infections, whether due to a virus of the influenza type, or to pyogenic bacteria, were observed to exert a detrimental influence on the clinical progress of the patient with bacillary dysentery just as they have on other diarrheal states. It is not logical to expect that such parenteral infections would yield to sulfaguanidine therapy. On the other hand, it was observed, more frequently than not, that under the influence of the drug, the stools became normal promptly and the intestinal tract appeared better able to carry out its work.

In the latter stages of acute bacillary dysentery or its sequela, it may be impossible to determine which of the difficulties encountered are due to a continuation of the primary bacterial invasion, to secondary invaders of the intestinal tract, to parenteral infection, or to damages within the intestinal tract due to the primary bacterial invasion. This complicates the problem of appraising the effectiveness of any chemotherapeutic agent used in acute bacillary dysentery or other diarrheal states.

No persistent states of "post-infection" intestinal indigestion developed in any of the patients in whom chemotherapy was started within 5 days of the onset of fever or diarrhea.

Those cases receiving the chemical early showed surprisingly little disturbance of digestion either during the period of active therapy or following recovery. In spite of this, however, it has seemed advisable to employ a bland diet, moderately restricted in amount, during the period of active treatment. There is some reason, based upon careful observation, to believe that those patients who were on a diet which was high in protein (casein), and which was moderately restricted in amount, presented the best and most prompt recoveries. Cultured lactic acid milk, cottage cheese, Philadelphia cream cheese, and custard, when given in moderate amounts, seemed to be the diet of choice. Vitamins, in powder form, were added to the cultured lactic acid milk and may, or may not, have influenced the recoveries.

Sulfaguanidine was most effective during the time when the dysentery bacilli were more active. It was least effective when the activity of these bacteria was absent and when their residua remained within the intestinal tract in the form of abnormal physiologic states. While the chemical effectively controlled the activity of the bacteria, it did not, by itself, correct damages already produced by the bacteria, or their toxins, once such damage was already established. By controlling the bacterial infection, sulfaguanidine may have aided such supportive measures as adequate fluid intake, intravenous glucose, calcium gluconate, transfusions of serum or whole blood, etc., so that they might, more effectively, correct attendant chemical pathology. It should be emphasized that sulfaguanidine did not and will not overcome acidosis, dehydration, fluid imbalance, or electrolyte disturbance.

When altered physiologic states, or those characterized by unusual chemical pathology, were already present before the institution of chemotherapy, it was necessary to employ measures directed toward these specific conditions. In the more protracted forms, and in the absence of such special measures, chemotherapy would undoubtedly have been much less effective.

Sulfaguanidine was not as effective in recurrent attacks of bacillary dysentery, nor in the more chronic forms, as it was when used within 5 days after the onset of the original attack. If, on the other hand, the stools contained blood or pus, and there were dysentery bacilli in the stools as shown by culture, the results were generally very good. It was difficult to predict what the result would be. At times, so striking and so prompt were the beneficial effects of the drug, in these forms of bacillary dysentery, that one cannot escape the conviction that sulfaguanidine should be administered in all forms of bacillary dysentery for at least 5 to 7 days in the manner recommended. If at the end of that time recovery is not apparent, then sulfathiazole or sulfadiazine should be given for 5 to 7 days. Some of the most amazing results so far encountered in the use of sulfaguanidine occurred in stubborn, serious cases of chronic bacillary dysentery.

Relapses, whether early or delayed, were extremely rare after the use of sulfaguanidine in the treatment of acute bacillary dysentery. Certainly this was in striking contrast to the frequency with which such conditions occurred in those who did not receive chemotherapy.

There was no reason to believe, either from the bacteriologic or from the epidemiologic standpoint, that the use of sulfaguanidine tended to "mask" infections of dysentery bacilli, or to complicate the community health situation by increasing the "carrier" rate.

In homes where outbreaks resembling the institution type of outbreak of bacillary dysentery occurred, it was possible, with sulfaguanidine, to control promptly and effectively, not only the individual cases, but also the spread of the outbreak as well. The chemical has great value as a control agent in outbreaks occurring among those whose living conditions are crowded, which so frequently are encountered in mining areas, in the poorer districts, and even in military camps and establishments. It is possible in an institution to check such an outbreak within a few days by giving everyone in the institution the chemical for a period of 5 to 7 days. It must be remembered that in so doing the maintenance dose should be employed and given only every 8 hours if the stools are less than 5 a day as they are apt to be in those not already stricken with the malady.

Sulfaguanidine is of definite value in reducing the number of days of illness due to bacillary dysentery. This gives it unusual importance in industrial and military medicine. Its wider use will result in a continuously lower dysentery mortality rate.

Early recognition and early treatment are just as important in the treatment of bacillary dysentery as the antibacterial activity of the chemical itself. Best results were definitely attained when chemotherapy was applied early in the disease.

Sulfaguanidine is quite as effective in the treatment of acute bacillary dysentery in adults as it is in infants and young children.

Chemotherapy has completely revolutionized the treatment of bacillary dysentery. Sulfaguanidine is quite as effective in the treatment of acute bacillary dysentery as sulfanilamide is in the treatment of some streptococcal infections or as the other sulfonamide compounds are in the pneumococcal infections. Besides its therapeutic effectiveness, the chemical is easy to give and has such a wide margin of safety that it is the ideal agent to use in the treatment of bacillary dysentery.

NOTE.—Since submitting this report, it has been possible to observe the treatment of 14 patients with severe or moderately severe bacillary dysentery, who were treated with succinyl sulfathiazole. In severity and in clinical characteristics these were in all respects similar to those previously described in a controlled study.[3] The initial dose was twice the maintenance dose. This in turn was 0.04 gram per kilogram of body weight every 4 hours if six doses were given daily, or 0.05 gram per kilogram if five doses were given daily at approximately 4-hour intervals. After the diarrhea had been "checked" for 72 hours the drug was discontinued. In this admittedly small series of cases, succinyl sulfathiazole appeared to have all the virtues of sulfaguanidine as to therapeutic efficacy and as to freedom from untoward effects. It was exceedingly well tolerated.—[G. M. L.]

MEDICAL ILLUSTRATION IN THE UNITED STATES ARMY*

Historical and Present Considerations

Captain Ralph P. Creer,† U. S. Army

It has been said that the only worthwhile result of any war is the great advancement that is produced in medical science. If this is true, then it follows that proper and adequate illustrations of these achievements are important.

Medical illustration in time of war is by no means new. The ancient Greeks and Romans produced illustrations of a medicomilitary nature (Fig. 1). As early as 1497 line drawings appeared in *The Book of Surgery*. One illustration entitled "The Wound Man" shows many types of injuries by various weapons and external agents, such as those acquired from a thorn, an arrow, a club, a knife, a sword, and similar devices (Fig. 2*A*). Another woodcut published in 1528 illustrates the disinfection of a wound by cauterization (Fig. 2*B*). The extraction of an arrow from the cardiac region by military surgeons was also depicted in 1528 (Fig. 2*C*).[2]

The surgical work of Ambroise Paré,[3] famous French surgeon, published in 1634, contains medical drawings. The *Memoirs* of Larrey,[4] surgeon to Napoleon, is illustrated with fine steel engravings of war wounds and instruments.

There are many other examples of early medicomilitary art. However, in the interest of brevity this paper is limited to medical art in the Army of the United States, beginning with the Civil War.

On Nov. 24, 1863 Gen. Joseph K. Barnes, Acting Surgeon of the Army, issued the following Circular Letter No. 26:

> The attention of Medical Officers in charge of U. S. A. General Hospitals is invited to the importance of preparing illustrations of the results of surgical operations. These can in many instances be conveniently obtained by means of plaster casts, which are readily made without subjecting patients to the slightest inconvenience.
>
> The casts most desired are those of stumps of amputations of every variety, and models of limbs upon which excisions may have been performed.

Soon after the War Between the States, *The Medical and Surgical History of the War of the Rebellion*[5] was published. This group of stately volumes gave

a clear visual idea of the type of wounds encountered, the means of surgical repair, and the many traumatic diseases which then as now were problems of all wars.

There were a number of contributors to these well-illustrated books. Of course, the early photomicrographic achievements of Col. J. J. Woodard, Major Curtis, and W. M. Gray are well known to students of photomicrography. William Bell, Charles Throught, and C. J. Blacklidge made most of the clinical and gross pathologic photographs.

The drawings were contributed by Baumgrass, Dr. J. C. McConnell, William Schultze, Edward Stauch, and Hermann Faber. The latter had a distinguished career as an artist. At the outbreak of the Civil War he enlisted and was assigned to the Surgeon General's Office as a medical artist, although rated as a hospital steward. He remained in the Service for five years and after the war returned to Philadelphia, where he continued to practice his profession. Together with his two sons, Ludwig and Erwin, and Louis Schmidt, he illustrated Piersol's *Human Anatomy*[6] and other important texts.

Special mention should also be made of Gen. George M. Sternberg, who served as a medical officer in the Civil War at the age of twenty-three. Bacteriology and photomicrography were his main interests and in his biography published in 1920 by his wife Martha[7] the following statement is found: "After our arrival at Fort Mason, Dr. Sternberg was not long in establishing at his own expense a laboratory for biologic research. It was here in 1881 that he demonstrated and photographed the tubercle bacillus, discovered by Professor Koch earlier in the same year. I am informed on good authority that this was the first demonstration of the organism in America."

He was the author of a textbook entitled *Photomicrographs and How to Make Them.*[8] In 1879 Sternberg published a well-illustrated atlas of photomicrographs. He later became Surgeon General of the United States Army.

Medical illustration in the United States Army received its greatest impetus during World War I. In June, 1917, Mr. Roy Reeve was assigned as photographer at the Army Medical Museum. Almost immediately the need for a more active service was recognized and in less than a year the personnel of this department was increased to approximately twenty. Their duties for the most part consisted of photostat copying, and a number of lantern slides were prepared for teaching purposes. This was the beginning of a permanent photographic department which has contributed ever since to the effective and efficient dissemination of medical knowledge.

In the same year, 1917, a medical art department was organized under the supervision of Lieut. William T. Schwarz and Lieut. M. L. Bauer; a motion picture section under the direction of Lieut. Thomas Evans also was started.[9] The function of the art department is best described in an article by Major R. W. Schufeldt published in July, 1918.[10]

> The scope of the Art Department was, when first put on foot, very modest, being principally confined to the making of a series of drawings and designs for use in motion pictures. Then man after man was added, each skilled in some special line, until at this writing there are first-

class painters in both oil and water colors; anatomical and pathological artists, histological artists, as well as modelers and casters, designers—indeed, technical artisans of nearly every sort known to the professions and trades.

Another field into which the output from this art department finds its way is the instruction of men and officers at the various cantonments and camps, in this country as well as in France. This is accomplished through the scientific use of the motion picture machine and the lantern.

Fig. 1.—The physician Iapyx extracting an arrowhead from the thigh of the wounded Trojan hero Aeneas. From a Pompeiian wall painting.

Competent medical officers, who are good instructors, are sent out on this work, equipped with projecting instrument, screen, and films or slides, and give a complete set of lectures at the camp or cantonment to which they are directed to proceed. This entire scheme has resulted in vastly improving the fitness and health of both officers and men of our army, and the amount of improvement so produced is now being very rapidly increased. Our art department has very substantially aided in this, and its assistance is being felt more and more each day that passes.

Most of the artists assigned were portrait or commercial painters with little or no knowledge of medical illustration. Therefore, a complete dissecting room was provided where these men made actual dissections upon a cadaver under the supervision of a competent anatomist and teacher.

The motion picture department was charged with the responsibility of producing instructive teaching films in relation to health for Army consumption. The original negatives were made by this department and a number of duplicate films were processed by the personnel. The motion picture "Fit to Fight" is an example of the type of film produced by the department; nineteen copies were distributed throughout the Army camps. Other two-reel anatomic pictures relating to veneral diseases were also made.

During the course of and directly following the last war two exceptionally worth-while texts were published. In each instance medical illustrations were of incalculable value.

A Manual of Surgical Anatomy[11] was authorized by the Secretary of War. Supervised by the Surgeon General, this manual was prepared at the University of Illinois and the illustrative work was executed under the direction of Mr. Tom Jones.

In 1920 a book entitled *Studies on Pathology of War Gas Poisoning* was published by Dr. Milton Winternitz. The work was done with the consent of the Surgeon General of the Army and the Chemical Warfare Service. This volume was well illustrated by Mr. Armin Hemberger, a medical artist at the Yale University School of Medicine.

Early in April, 1918, Col. Louis B. Wilson reported to France for duty as Director of the National Army Medical Museum Unit. Soon after his arrival he visualized the need for a competent medical illustration service and in May, 1918, a request was made for clinical photographers and artists who were already on duty at the Army Medical Museum in Washington. This request was disapproved by the general staff "in view of the existing tonnage situation, and in the belief that the requirements could be successfully handled by the Signal or Engineering Corps."

An attempt to locate qualified personnel in these organizations proved futile. Thus, a second request was made to the War Department and finally on Sept. 14, 1918, one officer and seven enlisted men arrived in France prepared to make motion pictures of war wounds and injuries. A few weeks later several medical artists and moulage experts reported for duty and a general illustration unit was established at Vichy in the central hospital laboratory of the Base Hospital Center.

Prior to the arrival of this last group a number of units had brought with them fairly good amateur photographers. However, in many instances these men were put into work entirely foreign to photography and considerable time was lost in effecting their transfer to departments where their photographic ability would be available to the medical service. Furthermore, Colonel Wilson encountered some difficulty in arousing interest in medical motion pictures. Most of the surgeons at that time did not see any value in motion pictures of surgical operations, and this particular branch of medical illustration was not encouraged.

Furthermore, General Orders No. 15, H., A. E. F., Jan. 24, 1918, limited the practice of photography in the American Expeditionary Forces to the Signal Corps. On May 25, 1918, another General Order was issued which amended the previous orders and charged the medical department with making

technical photographs of surgical and pathologic interest. In order to carry out this responsibility a survey of the medical department was made to ascertain the availability of suitable photographic equipment.

Because of the previous ban on photography by the Medical Department practically no hospitals were found equipped with sufficient apparatus or materials. A few cameras were procured from French sources, three were borrowed from the Signal Corps, and twenty-four from the roentgenologic department of the professional service. When finally equipped this group produced thirty-five casts of surgical cases, about 200 drawings, and more than 1,000 photographs of technical subjects prior to the signing of the armistice of Nov. 11, 1918, approximately three months of actual service.

Although the Signal Corps had been authorized in March, 1918, to illustrate the medical history of the war, they had been able to cover but little of the medical activities of the American Expeditionary Force, except for popular subjects which were used for propaganda purposes. After the signing of the armistice, and as soon as the clinical photographers could be released from their duties with combat divisions, they cooperated with the Signal Corps in illustrating the medical history with still and motion pictures. This bureau made more than 10,000 still pictures and about 40,000 feet of motion pictures of hospital activities, hospital locations, and group and individual pictures of the medical officers of the General Staff.

As a result of his knowledge of the organization difficulties which were encountered during the First World War, Colonel Wilson wrote in the February, 1920, issue of the *Military Surgeon*[13] as follows: "Restrictions on photography, such as operated early in the history of the A. E. F. so greatly to hamper the activities of the Medical Department, would seem to be unnecessary for safeguarding information, the Laboratory Division no doubt being as trustworthy as the Signal Corps. Preparation should be made in peace time for the selection of trained personnel for the various highly specialized functions which must necessarily be performed. Provisions should also be made for a standard photographic equipment to be supplied to the laboratories of various types. Special attention should be paid to photographs of methods of handling the wounded and of the appearance and treatment of battle injuries in forward areas, an adequate knowledge of the conditions of which is so essential and yet so difficult to convey to the inexperienced medical officer."

Similar ideas were suggested and the value of medical illustration in time of war was outlined by the author in a paper presented at the Annual Convention of the Association of Military Surgeons in October, 1938.[14]

At the request of the Surgeon General's Office the Biological Photographic Association in 1940 furnished a list of competent and qualified clinical photographers. Mr. Tom Jones and Mr. Jack Wilson cooperated in supplying a similar list of medical artists.

Early in 1942 Col. J. E. Ash, Curator of the Army Medical Museum, was charged with the responsibility of organizing the "Museum and Medical Arts Service." The purpose of this newly formed unit is to provide an adequate

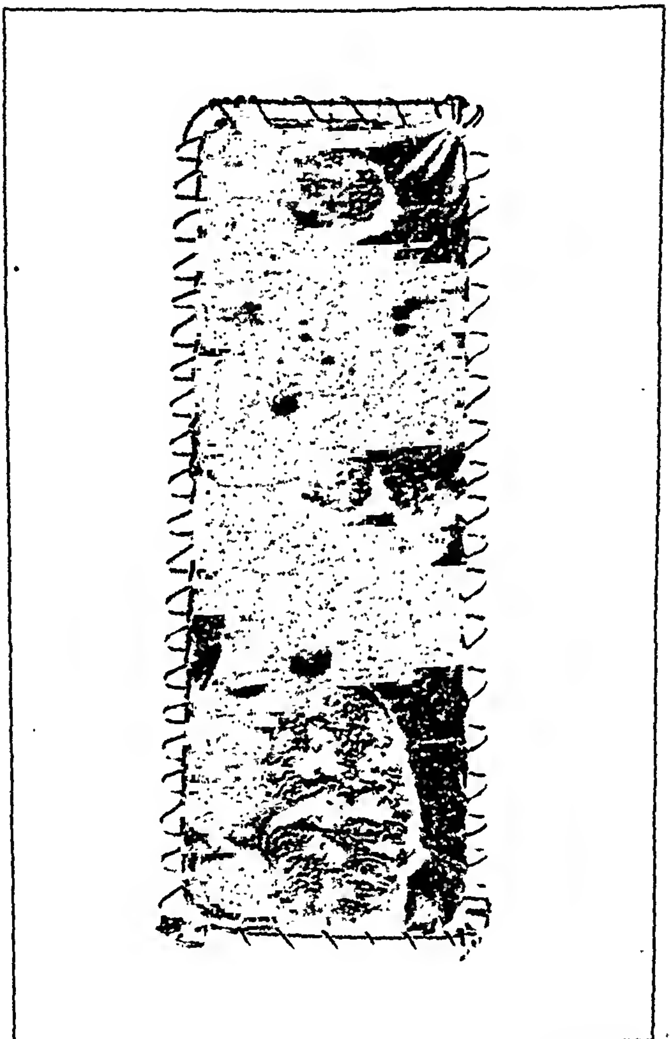
and efficient illustration service for the Medical Corps. This new organization is attached to the Museum for training purposes and all material collected by such units will be shipped to the Museum, where it will be available for study and research.



THICKENED PEYER'S PATCHES.

No. 380 MEDICAL SECTION.

Fig. 4.—Photograph of a gross specimen. (*Medical and Surgical History of the War of the Rebellion.*)

In addition to the illustration activity this organization will also be responsible for the collection of missiles and helmets that have been struck by gun or shell fire, of medical and surgical instruments of American, allied or enemy origin, especially those which have been developed or materially

modified during the progress of the war, and of any other similar apparatus that might prove of historical value. Pathologic specimens are also to be included in the collection.

Units will be attached to the larger medical installations in the various important theaters of operations and will be under the direction of the surgeon of each theater. It is highly probable, therefore, that a unit may be temporarily divided and a photographer or artist ordered to cover an individual assignment.

Provisions have also been made for the employment of a limited number of Civil Service personnel. These men or women will be attached to the larger general hospitals within the continental limits of the United States and will be assigned wherever their services are required.

These units will be equipped with still and motion picture equipment, together with material to produce color as well as black-and-white photographs. Suitable and adequate art supplies will be furnished to the medical artists. All of the photographic supplies and most of the art materials will be furnished by the Signal Corps while in the theater of operations.

Arrangements have been made whereby the Signal Corps facilities will be available for photographic processing. Proper labeling and the identification of all illustration material is of the utmost importance, and each man is specifically instructed in this regard.

The qualifications of the officers in charge of each unit will be of special interest, and the following is a brief, concise outline of the requirements.

1. It is essential that the officers have a rather broad training with experience in the field of medical illustration, particularly photography.

2. They must be experienced in supervising, planning and directing the activities of a medical illustration department.

3. According to The Adjutant General's Office, applicants for a First Lieutenant in the Sanitary Corps must be at least thirty years of age, have a college degree, and, of course, there is always the matter of an Army physical examination.

4. Last, but by no means least, the candidates must be *officer material.* In that phrase is embodied a number of qualities which are quite aside from the professional requirements, but are extremely important to the success of an officer and his entire unit of men.

With regard to the enlisted men, thus far we have been able to select men who have served as assistants in various medical photographic and art departments throughout the country. Most of them were already in the armed service prior to the organization of the Museum and Medical Arts Service, and it was necessary to effect a transfer so that their special training would be available to the Medical Department. In other instances, they have been enlisted for duty at the Army Medical Museum.

In any event, it is essential that each enlisted man receive the required three months' basic military training at an Army camp.

The same requirements hold true for the artists. The majority of the artists now on duty have had formal training in medical art. A great many portrait and landscape artists have applied in writing or in person. One of our

greatest problems is the matter of explaining the fact that medical illustration requires a special type of training decidedly separate and distinct from the usual academic art course.

At present the artists on duty at the Army Medical Museum are undergoing a training program especially designed to help those who require further instruction in surgical drawing and moulage. They are also preparing basic anatomic drawings for the surgical service of the Surgeon General's Office. In addition, these men prepare drawings of unusual gross specimens which are shipped to the Museum from various Army medical centers. Their cooperation is also solicited in the preparation of scientific exhibits.

The photographers receive training and actual experience with the apparatus and materials which will be employed in an overseas assignment. The photography of patients, gross specimens, and surgical operations will account for the greater portion of their work. There will also be a limited amount of photomicrography.

Although the professional relationship between the medical artist and clinical photographer has shown a decided change for the better in recent years, nevertheless there is still much room for improvement. The majority of enlisted personnel attached to the Museum and Medical Arts Service are younger men. It is necessary that they drill together, work together, often live in the same barracks, and enjoy the same recreational facilities. As a result, it is only logical to assume that in the future men in this profession will enjoy a better understanding and appreciation, and a keener respect for each other's specialty.

Inasmuch as both officers and enlisted men will eventually be assigned to military hospitals or field units, a military training program is essential. This program consists of lectures, training films, and drill formation.

The Training Division of the Surgeon General's Office is working on a plan whereby realistic full-size wax models of various war injuries will be used to demonstrate the actual appearance of war wounds to the enlisted men of the Medical Corps. In addition, duplicate casts will be prepared of latex or a suitable substitute. These thin, sleeve-like appliances, molded and colored to simulate actual war injuries, can be affixed to the arm, leg, or other parts of the body. Worn by men on maneuvers they will convey a realistic sight of what may be encountered on the scene of action. Dressings, splints, and tourniquets may be applied and later checked by the Medical Department instructors.

From the foregoing it can be concluded that the Medical Corps is fully aware of the importance of medical illustration, especially in time of war. Careful preparation and planning have been accomplished, and we are now ready with suitable equipment and trained personnel to meet the illustration needs of the Medical Corps. Obviously this entire program places in the hands of the Medical Department the same powerful documentary and educational implement of visual description which is rapidly revolutionizing the entire teaching profession.

WAR AND DISEASE

RALPH H. MAJOR, M.D., KANSAS CITY, KAN.

DISEASE profoundly influences the course of men's lives. Man, from the day of his birth to the day of his death, is in constant battle against disease, either warding it off or trying to conquer it. Disease has determined the migration of races, their colonial expansion, their geographical distribution. It has conquered armies, overthrown empires, and changed the course of history.

In times of peace, as well as war, great epidemics have left their mark upon the history of nations. The fall of the Venetian Republic was caused as much by the constant incursion of bubonic plague as by the armed attacks of her warlike neighbors. The Black Death in England produced as great a revolution in the social and economic life of Britain as all the wars that hardy island waged. The terrific toll the plague took among priests and higher ecclesiastics necessitated the filling of these depleted ranks by ill-trained and often ignorant peasants. Many historians have considered that these clerics, possessed of little respect for the prerogatives of the clergy and more concern for the lot of the common people, were among the most powerful influences leading to the English Reformation.

Dramatic as are the changes produced by disease during times of peace, the effects of disease in times of war are even more cataclysmal. Wars spread disease, and disease, in turn, destroys warriors. Epidemics in past wars have only too often destroyed armies and left nothing behind but a melancholy

account of their progress. In some wars, epidemics, although they have destroyed thousands, have left some clue that enables later generations to conquer or to prevent them. In other wars we have the melancholy picture of the deaths to thousands which could have been prevented by the intelligent application of measures already known to medical science. This picture, unfortunately, appears with distressing frequency as we turn the pages of medical history.

The great plague of Athens was one of the most dramatic episodes in the history of civilization. Whether this was a bubonic plague, as Francis Adams of Banchory, who was not only an eminent physician but an outstanding Greek scholar, asserted, or whether it was typhus fever or scarlet fever as others maintain, is beside the point. The Athens of Pericles presented a level of culture and intelligence never before or since equalled. Within the walls of this city of some two hundred thousand, lived and worked the dramatists Aeschylus, Sophocles, Euripides, and Aristophanes; the philosophers Plato, Xenophon, and Anaxagoras; the sculptors Phidias, Praxiteles, and Polygnotus, and the historian Thucydides. When the Spartan king Archidamus attacked Athens, Pericles followed what is called today a "scorched earth" policy. He withdrew all his soldiers and people from the outlying country and they swarmed into the walled city of Athens for protection. The housing conditions were inadequate, and the food supply was insufficient; the proper disposal of refuse became impossible, and the water supply became contaminated. Then, like a thunderbolt, the plague appeared with all its horrors which have been so graphically described by Thucydides, an eye witness of the harrowing scenes.

The Spartan king prudently withdrew and attacked elsewhere. He feared the epidemic might spread into his own army, and he also wisely reckoned that the plague would destroy more Athenians than could the Spartans. According to some authorities, the first wave of the epidemic destroyed one-third of the inhabitants of Athens; according to others, two-thirds. After the first wave had subsided somewhat, Pericles sent an expedition to capture Potidaea and harass the Spartans from the rear. This expedition, if successful, would have changed the entire course of the war. Unfortunately, the men carried the seeds of the pestilence with them and, before the ships reached Potidaea, the disease raged among the soldiers and sailors, and the fleet was compelled to return to Athens. Pericles then planned another brilliant stroke. He sailed with his troops to Epidaurus, hoping to capture that city and again strike the Spartans from the rear. This expedition was also a dismal failure because, according to Plutarch, "the distemper which prevailed in his army broke all his measures, for it not only carried off his own men, but all that had intercourse with them."

Athens slowly went to her doom. When the plague struck down Pericles himself, no leader of equal ability arose to take his place. Finally, the Spartan admiral, Lysander, sailed into the harbor of Piraeus; the Spartans tore down the long walls of Athens to the merry tune of Spartan flutes, and young Spartan women danced gaily to the music while the Athenians filled the air with wails and lamentations. The Athenian Empire was humbled to the dust, never to rise again. The plague of Athens had played a catastrophic part in her defeat, and had left no clue to prevent similar catastrophes.

Unfortunately, the historians of the Peloponnesian War—the war between Athens and Sparta—were not medical men. If Hippocrates, as well as Thucydides, had described the plague of Athens, there would probably be no uncertainty concerning the nature of this epidemic. Fortunately, some of the epidemics accompanying later wars were described by surgeons in varies armies with such accuracy and fidelity that the diagnosis is certain.

Few wars in history have lasted so long or have been more destructive of life and property than the Thirty Years' War. This war, which began as a struggle between Protestants and Catholics, became a war in which the Protestants of Germany and Sweden were allied with Richelieu, the great Catholic prelate, in the struggle against Catholic Austria. This war was a "total war" in the modern sense. Far more civilians—men, women, and children—were destroyed than soldiers. Germany, according to some authorities, lost one-half of her entire population; according to others, two-thirds. A century and a half passed before the population of Germany reached its pre-war level.

The Thirty Years' War is commonly divided by historians into the Bohemian period, the Palatine period, the Danish period, the Swedish period, and the French period. The medical historian, Prinzing, divides it into the typhus period and the plague period.

The disease which carried off so many victims in the early part of this war was the notorious Hungarian disease, a disease accurately described by Tobias Cober, who served as surgeon in the army of Rudolf II, King of Hungary, in the wars against the Turks. He notes that the disease raged especially in camps heavily infested with lice, and his description leaves no doubt that it was typhus fever.

Measures were taken by certain cities to prevent the twin pestilences, typhus and plague, from entering. In Munich, for instance, the city fathers shut the city's gates against all strangers, disinfected all incoming letters, and washed with vinegar all the money that came in. These measures stayed the hand of the plague for a time but presently, infected Spanish soldiers forced their way into the city and spread the disease among the inhabitants. More than one-half the population died from the plague in a few months.

Many great generals, Tilly, Wallenstein, and Gustavus Adolphus, perished in the course of the war. When we balance the results of this war in the terms of great victories, territory gained, and prestige enhanced, as against the losses through pestilence, we may safely conclude that the real victors were typhus and plague.

Napoleon, the greatest military genius of the nineteenth century, was really defeated before Waterloo; he was defeated by his ill-starred campaign in Russia. The Grand Army, to quote Larrey, Napoleon's great surgeon, set out for Russia 400,000 strong. Six months later this army, retreating from Russia, finally reached Gumbinnen in East Prussia, numbering only 3,000.

This disastrous adventure of Napoleon has been described in every history of Europe. The bloody battles, the intense cold, the ferocity of the Russian Cossacks, have all been stressed as the cause of Napoleon's defeat. The role played by disease was even more important. Typhus fever seems to have played the major role, ably assisted by typhoid and dysentery.

The accounts left by the surgeons in Napoleon's army give us a clear picture of the devastation caused by disease. One of the most dramatic was written by Kerkhoffs, a Dutch surgeon attached to the Third Army Corps of Marshall Ney. This Corps, Kerkhoffs relates, was finally reduced to twenty men, as the result of privation and disease. In discussing the failure of the campaign, Kerkoffs remarked that if Napoleon had contented himself with occupying Poland and organizing sanitation there, the campaign would have succeeded and changed the whole course of history.

But Napoleon was in a hurry. In spite of bloody battles and ever-increasing number of sick, he pressed on to Moscow, carrying wagon loads of infected soldiers into that city, leaving the desperately sick in towns and villages where they infected the new troops pressing on eastward.

Sergeant Bourgogne of the Grand Army wrote an interesting account of the march into Russia. He was particularly impressed by the large number of vermin he saw. He went to sleep on a reed mat in a little town of Poland. Presently he awoke from his slumber and finding himself covered with lice, stripped off his shirt and trousers and threw them into the fire. There were so many of these animals on his garments that they "exploded like the fire of two ranks of infantry."

The role of lice in the production of typhus fever was not discovered until a century later. However, Napoleon's surgeons write so much about lice that we wonder if they did not suspect them. They were aware, however, that typhus was highly contagious. One surgeon observed that York's Prussians, who had not been in Moscow at all, had no cases of typhus fever until they followed the retreating French. Another army corps had no typhus until it passed along a road previously used by the French. After a march of fourteen miles on this road, there were fifteen to twenty men in each company ill from this disease.

Napoleon's disaster in Russia was not the first time he had been defeated by disease. His previous campaign in Syria had ended in retreat before an advancing epidemic of bubonic plague. History records that Napoleon mingled freely among the plague-infested soldiers at Jaffa to show his contempt for the disease and that his surgeon, Desgenettes, inoculated himself with pus from the buboe of a sick soldier, to prove that the disease was not contagious. Desgenettes remained perfectly well, probably because, as we now know, the pus from plague boils often contains very few plague bacilli.

The ravages of typhus, typhoid, and dysentery did not cease with the end of Napoleon's Russian campaign. The retreating army scattered pestilence far and wide. Typhus fever broke out in East Prussia and caused the death of 20,000 inhabitants. From East Prussia it spread rapidly to other parts of Germany, to Silesia, Saxony, Bavaria, and the Rhineland. Prinzing estimates that 10 per cent of the population of Germany contracted typhus fever, and 200,000 to 300,000 died. From Germany it spread to France, where it also caused an appalling toll. In Metz all the physicians contracted the disease and many of them died. In the Department of Moselle alone, more than 10,000 died from typhus, this figure not including soldiers.

Typhoid fever, long confused with typhus, has caused a greater number of deaths than typhus in the armies of nations whose hygienic standards do not tolerate the presence of lice.

In the American Civil War, 186,000 troops of the Union Army died of disease as compared with 44,000 killed in battle and 49,000 who died of wounds. Typhoid fever caused the death of 36,000 soldiers.

The health record of the American Army during the Spanish-American War gives us no cause for pride. During this minor struggle sixty-seven officers and 1,872 men died of disease, and twenty-nine officers and 440 privates were killed in action. The death rate in the army camps became so high as to constitute a national scandal. A commission headed by Walter Reed. was appointed to study sanitation in the army camps. They found that "more than ninety per cent of the volunteer regiments developed typhoid fever within eight weeks after they came into camp."

The report of this commission remains a monumental contribution to our knowledge of typhoid fever. They found that the most important carriers of the infection were flies, which feasted on the dejecta of patients and then crawled over the food in the mess halls. Ignorant, untrained hospital orderlies also spread the disease. Without even washing their hands, many of these orderlies left the hospital wards and walked into the mess hall where they prepared food for the soldiers.

The typhoid bacillus was discovered eighteen years before the Spanish-American War, the Widal reaction had been in use for three years, the mode of infection and methods of prevention had long been known. Yet in an army of 107,973 men, there were 20,738 cases of typhoid fever.

The Boer War was an even greater blot on the pages of the history of sanitation. The British had apparently profited little by the American experience. In this war, the British Army lost 22,000 men, of whom 8,000 had been killed in battle or died of wounds, while 14,000 died of preventable diseases. There were 57,684 cases of typhoid fever with 8,022 deaths. The typhoid bacillus had killed more men than the Boers.

The high typhoid fever rate in the British Army during the Boer War, seems inexcusable in the light of present knowledge. Three years before the Boer War, Wright had demonstrated the protective value of antityphoid vaccines, and two years later had inoculated four thousand men of the British Indian Army, with excellent results. The British Army in South Africa authorized—permitted is perhaps a better word—voluntary vaccination. The vaccination was carried out in a rather haphazard fashion, records were poorly kept and often lost. The army authorities finally forbade the inoculations altogether.

Two years after the close of the Boer War a Royal Commission appointed to study the value of antityphoid vaccination issued a favorable report which rehabilitated the procedure of antityphoid inoculation. It came too late to aid the typhoid victims of the Boer War, but it carried a poignant message to the armies in future wars.

With the turn of the century there came a turn in the health record of armies engaged in war. During their war with China in 1894 and 1895, the Japanese lost four times as many soldiers from disease as from bullets. Indeed, this had been the record of armies for decades. These figures appalled the Japanese government, which reorganized its military medical service and

sent thousands of young Japanese all over the world to study the latest advances in sanitation. Japan, to quote Major Seaman, writing in 1905, "even had the temerity (strange as it may seem to an English or American Army official) to grade her medical men as high as officers of the line, who combat the enemy that kills only 20 per cent."

The report of the Japanese Army at the end of the Russo-Japanese War showed the wisdom of their policy. Seven per cent died in battle; 1.5 per cent died of disease.

The first World War proved that the United States Army had profited by its own mistakes in the Spanish-American War and by the mistakes of the British in the Boer War. The lessons of the Russo-Japanese War had also been studied and learned.

Typhoid fever, the great scourge of past wars, claimed only 213 victims in the American Army of 4,000,000. If the typhoid death rate of the Spanish-American War had prevailed, more than 68,000 soldiers would have lost their lives from this disease. Surgeon General Ireland of the United States rightly attributed this decline to vaccination and improved sanitation, including careful examination of cooks and food handlers.

Tetanus caused only four deaths in the American Army, less than two out of every hundred thousand wounded. This figure is especially noteworthy, since the British in the early years of the war had 32 cases in every thousand wounded. Prophylactic injections of tetanus antitoxin in all the wounded explained the astonishing American figures.

Typhus fever did not cause a single death in the American Army. The figures from Russia were quite different and, indeed, appalling. During the war and the succeeding revolution, sanitation broke down completely in Russia. There were more than twenty million cases of typhus in Russia, with three million deaths.

The medical experiences of the World War demonstrated the great advances made in the prevention, control, and cure of certain infectious diseases. Two great groups of diseases remained, however, untamed. "The sputum-borne infections," observed Colonel Garrison, "particularly the pneumonias, remained the insoluble problem of the war." To this must be added streptococcic infections, which caused 70 per cent of the fatal infections in the British Army. The discovery of the therapeutic effect of the sulfonamides in 1933 bids fair to mark the beginning of the solution of what Garrison called the insoluble problem of the World War.

While we think of disease and war, we are prone to think only of infectious diseases and gloss over or neglect the role that disease due to faulty or insufficient nutrition plays. Prominent among these diseases is scurvy.

Scurvy appeared in the armies of the First Crusade. Jacques de Vitry, one of the crusaders, wrote an excellent account of this disease as it appeared at the siege of Damietta in 1219, and notes that it was a "pestilence, against which the doctors could not find any remedy in their art." Later in the Seventh Crusade of 1248, the army of Louis IX of France was attacked by this disease, and no one, reading the account of Sieur de Joinville, can doubt that scurvy was largely responsible for the disaster that befell Louis' army.

In 1535 Jacques Cartier's expedition to Canada suffered greatly from scurvy and probably would have perished to the man, except for the aid of the Indians, who told him that a decoction of the bark and leaves of the fir tree would cure the disease. Cartier's physicians had been powerless in the extremity, so we can understand his oft-quoted remark that the decoction of fir "wrought so well, that if all the physicians of Montpellier and Louvain had been there with all the drugs of Alexandria, they would not have done so much in one year as that tree did in six days."

The work of James Lind, who found that lime juice added to sailors' rations would prevent scurvy, is one of the great discoveries in medicine. Yet, incredible as it seems today, Lind waited forty-two years before he saw his measure put into effect by the British admiralty. The French seemed even more blind than the British to the importance of Lind's discovery. Larrey relates that Napoleon's army in Egypt was decimated by scurvy in 1799, incidentally forty-six years after Lind's discovery. The addition of lime juice to the rations of the French soldiers in Egypt might have proved a decisive factor in the campaign.

Since the demonstration that citrus fruits, added to rations, prevents scurvy, this disease has lost its military importance. In the recent Italo-Ethiopian War, there was not a single case of scurvy in the Italian Army, although the Ethiopian Red Cross reported over thirty thousand cases of scurvy on the Somaliland front alone.

The medical history of the present war remains to be written. Much can happen in the domain of diseases as well as in the field of strategy. Thus far, the glimpses we have had are encouraging.

The plaster of Paris method of treating wounds, as advocated by Orr and given a wide application in the Spanish Civil War, has had a marked effect in lowering the death rate from compound fractures. The sulfonamide drugs have been employed with gratifying effects in streptococcus infections, in pneumonia, and in meningitis. Sulfathiazole has proved a great value in curing as well as in preventing gonorrhea, a disease which in the last war kept several divisions constantly hospitalized.

Typhus fever in the present war has not been a serious menace. An epidemic of typhus has not appeared in Serbia as in the last war, probably because sanitation has improved there and the Germans are remembering the lessons of the previous epidemics. The same also holds for the occupied portions of Russia. The great epidemic in Russia during the last war appeared principally during the chaos of revolution.

While it is apparent today that methods of destroying life are more effective than ever before in history, it is comforting to the physician to know that methods of saving life are more numerous and more effective.

BOOK NOTICES

Books Dealing With War Medicine

War Medicine*
A Symposium

IT IS appropriate in the present emergency to republish collected papers on a subject of such tremendous immediate importance as war medicine, papers which have been scattered in a dozen or more journals, some in this country, some in Canada, and many in England. Most of the authors who have written on subjects dealing with war medicine are now actively engaged in the war. It would be folly to ask them to contribute rehashes of what they have already written, merely for the sake of calling it a new and original contribution. Such a procedure would not contribute to the prosecution of the war. The republication of outstanding contributions has been adapted with some of the articles appearing in the two War Medicine Numbers of THE JOURNAL OF LABORATORY AND CLINICAL MEDICINE in order to supplement and round out the symposium of original contributions.

The volume under review, "War Medicine, A Symposium," edited by Commander Pugh and Doctors Podolsky and Runes, is especially effective in presenting the most recent advances in war surgery. This fills approximately two-thirds of the volume. There are two other sections, "Aviation and Naval Medicine" and "General Medicine." The collected writings round out the entire field, but the volume is recommended especially for those dealing with war surgery.

A Short History of Nautical Medicine†

READERS of Captain Roddis' *A Short History of Nautical Medicine* will not be limited to naval physicians. This thoroughly interesting volume will appeal to army physicians as well as to naval medical men, to nonmedical naval men and seafarers in general, to historians and to nutritionists. Starting with the sparse records of maritime medical service used by the ancients, it traces the contributions in this field down to modern times. Captain Roddis lists some of the most important as (1) the conquest of scurvy (a fascinating story); (2) the distillation of drinking water; (3) the introduction of smallpox vaccination among sailors; (4) improved personal hygiene; (5) the institution of quarantine (and we learn here that the word is derived from the forty days of detention); (6) improvements in ventilation on shipboard; (7) the institution of preliminary physical examinations; (8) improvements in medical service on shipboard; (9) the development of naval hospitals and hospital ships, etc. The author develops the history of nautical medicine during the last few hundred years, especially through the story of the British Navy and the United States Navy. The book abounds in interesting anecdotes, especially in these two groups.

*War Medicine. A Symposium. Editor Winfield Scott Pugh, M.D., Commander, M. C., U. S. Navy, Retired; formerly surgeon, City Hospital, New York; Associate Editor Edward Podolsky, M.D.; Technical Editor Dagobert D. Runes, Ph.D. Cloth, 565 pages, $7.50. F. Hubner & Company, Inc., New York, 1942.

†A Short History of Nautical Medicine. By Louis H. Roddis, M.D., Captain, Medical Corps, United States Navy. Cloth, 12 illustrations. 359 pages, $3.00. Paul B. Hoeber, Inc. Medical Book Department of Harper and Brothers, New York and London, 1941.

Medical Manual of Chemical Warfare*

THE *Medical Manual of Chemical Warfare* is a reprinting of an official British manual. It contains a general description of war gases and detailed discussion of the different types, such as blister gases, choking gases, paralyzing gases and harassing gases. The list is quite complete. The volume describes methods of protection, recognition, and first-aid treatment. With deep regret we are forced to say that this volume will probably be very useful in the next years. The approach is clinical and practical.

What the Citizen Should Know About Wartime Medicine†

THE most recent of a series of twelve volumes to date of *The Citizen Series* is *What the Citizen Should Know About Wartime Medicine.* The books include subjects, such as what the citizen should know about the Army, the Navy, the Coast Guard, the Marines, Air Forces, Civilian Defense, submarine warfare, etc. Colonel Darnall and his associate author, V. I. Cooper, have given us an adequate presentation of the many functions of the medical services in the armed forces. This includes the organization of the medical department, aviation medicine, military psychiatry, sanitation, hygiene, the prevention and control of infectious diseases, the venereal disease problem, and war surgery. So much must be said in these fields that there is no space for history of the development of medical problems in past wars.

The book is written primarily for the layman. The diversified activities of the medical departments sometimes make it difficult for an officer in the medical service assigned to a highly specialized task to realize how many other problems are being prosecuted in his own department of the Army or Navy. For this reason, the volume will make interesting reading for men in the medical services.

Dermatologic Therapy in General Practice‡
Manual of Dermatology

TWO books on dermatology, written in part for the services, should be reviewed together, not so much because Dr. Sulzberger is coauthor of both books but because in actual practice the volumes will be found to be supplementary to each other.

The *Manual of Dermatology* has been issued under the auspices of the Committee on Medicine of the Division of Medical Scienes of the National Research Council and written by Donald M. Pillsbury, Marion B. Sulzberger, and Clarence S. Livingood. Prefatory notes by the Surgeon Generals of the Army and Navy explain the need for such a volume for use in the armed services. Nearly 10 per cent of all admissions to sick list and 10 per cent of all days lost on account of sickness are due to dermatologic maladies. This volume is in essence a vade mecum for physicians who are called upon to treat skin diseases. Most of the information and directions are tabulated and are very brief. The illustrations are so numerous and so excellent as to make it almost a dermatologic atlas. Important directions and cautionary remarks are emphasized by being boxed in.

The other volume *Dermatologic Therapy in General Practice* by Lieutenant Commander Marion B. Sulzberger and Dr. Jack Wolf is somewhat larger but is still of conveniently small size and presents adequately minute details of the methods of applying treatment

*Medical Manual of Chemical Warfare. Reprinted by permission of the Controller of His Britannic Majesty's Stationery Office, revised edition, 1942. Cloth, 121 pages, $2.50. Chemical Publishing Company, Inc., Brooklyn, N. Y.

†What the Citizen Should Know About Wartime Medicine. By Joseph R. Darnall, M.D., Lieut. Col., M. C., U. S. Army; and V. I. Cooper. Illustrations by André Fandot. Cloth, 227 pages, $2.50. W. W. Norton & Company, Inc., New York, 1942.

‡Dermatologic Therapy in General Practice. By Marion B. Sulzberger, M.D., Lieut. Comdr., M. C., U. S. N. R., Assistant Clinical Professor of Dermatology and Syphilology, Skin and Cancer Unit of the New York Post-Graduate Medical School and Hospital of Columbia University; Associ[illegible] iogist, Montefiore Hospital, New York City; and Jack Wolf, M.D., [illegible] and Syphilologist, Skin and Cancer Unit of the New York Post-Gr[illegible] and Hospital of Columbia University; Director of Dermatology, New York City Cancer Institute. Cloth, 632 pages. The Year Book Publishers, Inc., Chicago, 1942.

Manual of Dermatology. Issued under the Auspices of the Committee on Medicine of the Division of Medical Sciences of the National Research Council. By Donald M. Pillsbury, M.D., Marion B. Sulzberger, M.D., Clarence S. Livingood, M.D. Cloth, 421 pages, $2.00. W. B. Saunders Company, Philadelphia & London, 1942.

which are briefly touched upon in the *Manual of Dermatology.* The approach to dermatologic therapy in this book is definitely different from that of most textbooks on skin diseases. While the importance of accurate diagnosis is recognized and diagnostic discussion appears in the second portion of the book, emphasis in the first part is placed upon selection of the appropriate treatment based upon the character of the skin manifestation rather than upon its nosologic classification. In other words, one can apply the appropriate type of treatment in the great majority of cases even though one may not have had sufficient dermatologic experience to make the correct diagnosis in some unusual dermatosis.

These two volumes will be of greatest value when used together.

Fundamentals of Psychiatry*

WHEN millions of men are drafted into the armed forces, large numbers of neurotics, psychoneurotics, and psychotics are bound to be overlooked in the preliminary draft appraisal and admitted into the Army, Navy, or Marines. The tremendous stress of service life even without the emotional problems of combat activity serves to bring out psychotic tendencies in many who might have gone years longer before becoming ill. Military psychiatry is a vast field in its own right. Dr. Strecker's small volume, *Fundamentals of Psychiatry*, is, as its name implies, a synopsis of the subject of psychiatry and methods of psychiatric examination and treatment, in which he has incorporated much discussion of psychiatric problems of wartime.

War Gases†
Their Identification and Decontamination

THE British book, *Medical Manual of Chemical Warfare*, reviewed elsewhere, presents a comprehensive discussion of the uses and damaging effect of war gases. The present volume by Morris B. Jacobs, formerly Lieutenant in the U. S. Chemical Warfare Service Reserves and Chemist in the Department of Health of The City of New York, presents a similar discussion which the reviewer feels is better classified. The volume deals first with the classification of the chemical agents, then with the physical characteristics and physiological responses to war gases, and next with the effect of war gases on inanimate material, such as food and water. There is a section on sampling of gases and methods for analytic determination of their nature. The final section deals with methods of decontamination. Before the war is over, this volume will probably be widely used as a quick reference manual.

Civilian Health in Wartime‡

DR. DIEUAIDE'S volume, *Civilian Health in Wartime*, is in great measure a treatise on preventive medicine applied to the individual and to groups, which would be equally readable in peacetime. Written primarily for the layman, it provides at the same time an excellent refresher or orientation manual for the physician, nutritionist, and public health worker. The author discusses the effect of war on civilian health. He gives considerable attention to nutrition and diet. He next discusses infectious diseases and methods of control.

The importance of proper clothing and housing conditions is discussed. Maternal and child welfare, as well as geriatric problems, are presented in an easily readable style which should be of real interest to the intelligent layman. Other subjects include recreation, occupation, morale, and a chapter about doctors and nurses, how they work and what they can be expected to accomplish.

CLINICAL AND EXPERIMENTAL

LESIONS IN THE TISSUES OF THE BODY FOLLOWING SULFONAMIDE THERAPY*

Herbert J. Schattenberg,† M.S., M.D., F.A.C.P., and William H. Harris, Jr., B.A., M.D., New Orleans, La.

Not since the introduction of arsphenamine and neoarsphenamine many years ago, has a therapeutic agent received such a welcome and cordial reception as when the sulfonamides were introduced to the profession. Originally introduced to combat serious and grave infections caused by the streptococci, especially *Streptococcus hemolyticus,* the value of these drugs was soon established in pneumonia, meningitis, various bacteriemias, genitourinary tract infections, bacillary dysentery and any number of other disease entities. There is hardly a single specialty in the medical profession which does not make use of one or more of the sulfonamide drugs. Unfortunately, the laity has become too well acquainted with these drugs, looking upon them as a cure for any and all ailments, and are therefore using them haphazardly and indiscriminately. Much harm has resulted in many instances from such usage.

As a matter of historical interest, one of the sulfonamides, sulfanilamide (para-amino-benzene-sulfonamide) has been known for many years. Gelmo,[1] working on the chemistry of azo dyes, made it synthetically in 1908. Eisenberg,[2] in 1913 called attention to the bactericidal properties of certain azo dyes. Among the various azo dyes tested were pyridium, chrysoidine, and scarlet red. In 1935 chemists working under Domagk[3,4] produced prontosil I and prontosil II. Prontosil itself possesses poor bactericidal properties, but when its molecule is broken down in the body, a potent product, sulfanilamide, is set free. Trefouel,[5] and Fourneau[6] in France confirmed the contention that the azo dye upon being broken down in the body liberates sulfanilamide. Interest in these

Received for publication, July 20, 1942.

†Now at the Medical and Surgical Memorial Hospital, San Antonio, Texas.

new drugs first developed in America in 1936. The work in this country by Mellon,[7] and Long and Bliss[8] is well known.

Nothing is definitely known about the therapeutic action of the sulfonamides. Theoretically, it may be assumed that the drug acts by: 1. A neutralization of bacterial toxins. 2. It stimulates the cellular and humoral defensive mechanism of the host against the infectious bacteria. 3. It acts as a germicide and destroys the invading and circulating bacteria. This is unlikely since it has been shown by Selbie[9] that simultaneous administration of para-amino-benzoic acid and sulfanilamide in experimental animals does not prevent a fatal outcome, the action of the latter being antagonized by the former. One molecule of para-amino-benzoic acid inhibits the action of 23,000 molecules of sulfanilamide. Janeway[10] has shown that the addition of small amounts of para-amino-benzoic acid to blood cultures inhibits the action of sulfanilamide and thereby permits the bacteria present to grow and flourish. This would seem then that sulfanilamide acts merely as a bacteriostatic agent, giving other defensive forces of the body an opportunity of assisting them in ridding the body of infection.

Many articles have appeared in the medical literature extolling the virtues of the various members of the sulfonamide group of drugs in the treatment of different infectious diseases. Practically every medical program offers one or more scientific papers describing new uses or discussing clinical results obtained with these drugs. As so often happens with new therapeutic agents which appear to accomplish unusually favorable results, no thought is given at first to the fact that in some instances they may also do considerable harm. This has also been true of the arsphenamines, cinchophen, atabrin, and many other drugs when they were first introduced. It is true that all new drugs are at first thoroughly controlled for toxicity and other properties. These tests are carried out, in the majority of instances, on normal experimental animals. Let us not lose sight of the fact that an experimental animal often reacts differently to a drug than does a human being. Of more importance is the fact that in the instance of the patient extensive injury may already have occurred in the important parenchymatous organs as a result of serious infectious disease. Naturally a drug which itself may be toxic adds insult to injury in such an instance.

Recently numerous reports have appeared in the medical literature describing unfavorable reactions and even death as a result of sulfonamide therapy. Various types of skin lesions, nephritis, focal necrosis, and acute yellow atrophy of the liver, involvement of the central nervous system, myocarditis, anemia, leucopenia, and various other conditions have been described.

Lesions of the skin appear as one of the most frequent complications and may be a manifestation of an allergic or toxic manifestation or otherwise as a drug idiosyncrasy. Wien and Lieberthal[11] describe a pemphigus, foliaceous-like eruption following the use of sulfanilamide and sulfapyridine. Weinstein and Domm[12] report a case of a patient with pneumonia receiving a total of 15 Gm. of sulfathiazole. The patient developed a severe, acute exfoliative dermatitis. "Other than an overwhelming toxemia resulting from the widespread and severe involvement of the skin, no satisfactory cause of death was found." Volini, Levitt, and O'Neil[13] present a case report and discuss cutaneous and conjunctival manifestations of sulfathiazole intoxication. The severity of skin

lesions with extensive necrosis is well shown and discussed in a case report by Klingensmith.[14]

Lesions of the liver in sulfonamide poisoning have not received the attention they deserve. This is probably due to the fact that in the majority of instances such a diagnosis is arrived at only at autopsy. It has been our experience that

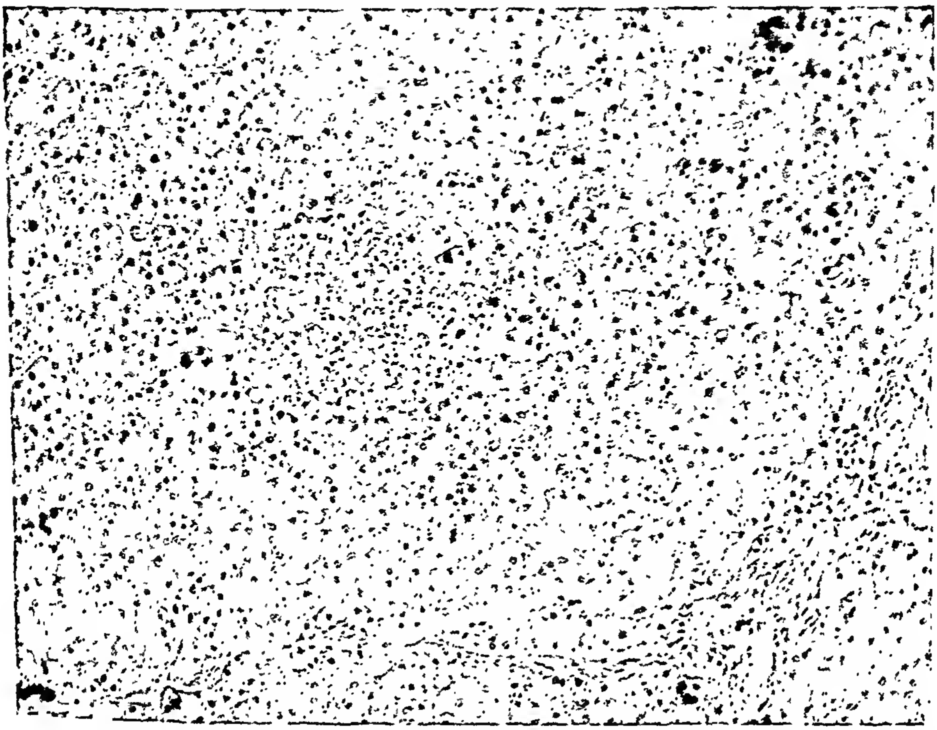

Fig. 1.—Photomicrograph of section of human liver. Note central area of focal necrosis. In other areas isolated liver cells likewise show necrosis. (×400.)

Fig. 2.—Photomicrograph of section of human liver showing extensive acute atrophy. Only a few isolated liver cells remain, and from the histology present it is difficult to tell that this is liver tissue. (×400.)

lesions in the liver are quite common and are frequently found at autopsy. The changes which we have noted at autopsy are severe cloudy swelling of liver cells, fatty degeneration, focal necrosis (Fig. 1), and in one instance there was encountered a case of acute yellow atrophy (Fig. 2).

Fig. 3.—Section of kidney showing tubules filled with blood cells and albumin casts. (×500.)

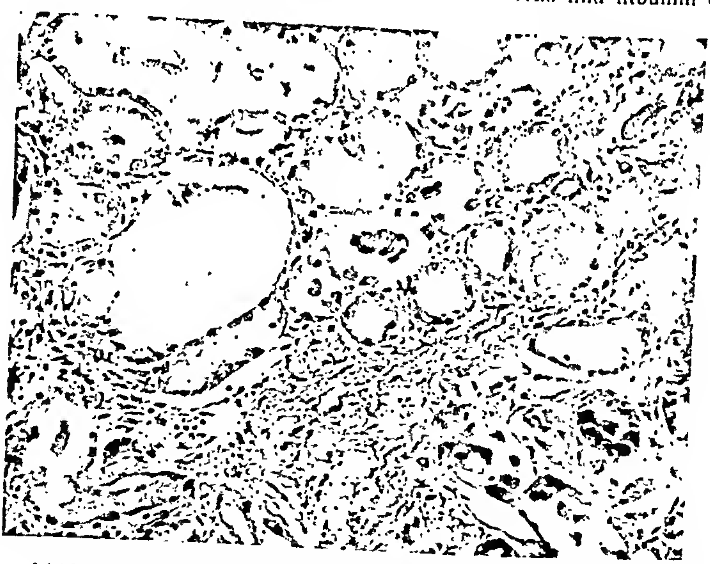

Fig. 4.—Section of kidney showing marked distention and dilatation of some of the tubules due to blockage by sulfapyridine crystals. (×500.)

The literature contains numerous reports of liver damage following sulfonamide therapy. Garvin[15] reports five cases of toxic hepatitis of patients who had primarily received sulfanilamide. A case of acute toxic necrosis of the liver following the use of sulfanilamide is described by Russell.[16] Watson,[17] in an excellent study, discusses the alteration of hemoglobin metabolism and hepatic function in a large series of cases receiving sulfanilamide and sulfapyridine.

Effects of these drugs upon the central nervous system are infrequently reported. One of the most recent reports is that of Little,[18] who describes the nervous and mental effects of the sulfonamides. Bieter and co-workers[19] carried out a series of experiments on chickens. Extensive peripheral nerve injury was noted. These investigators also present a case report wherein a patient developed deafness and loss of function of the right lower extremity following the use of sulfathiazole. These symptoms disappeared and function was restored after the drug was discontinued.

Fig. 5.—Gross picture of monkey's kidneys, ureters, and urinary bladder. Note marked ureteral dilatation and hydronephrosis on right due to blockage by sulfapyridine deposits. Ureter on left had been opened longitudinally and shows normal diameter of this structure.

Kidney injury is one of the most common complications encountered in patients receiving sulfonamide therapy. Instances of anuria, hematuria, nitrogen retention, and renal colic have been reported. Tubular casts we have noted are not an uncommon finding (Fig. 3). The insoluble acetyl derivative of these drugs forms crystalline deposits which may block the tubules (Fig. 4) or be so extensive as to cause ureteral blockage with hydronephrosis. It has been shown by Schwartz and co-workers[20] that crystalline precipitation is more likely to occur in acid urines. In a series of patients 28 per cent of those with alkaline urines showed crystalluria, while 70 per cent of those with an acid urine showed a similar precipitation. Alkalinization, therefore, seems an essential procedure to prevent precipitation and urinary tract blockage. The appearance of the

urinary acetyl derivatives of the various sulfonamides is well shown in the discussion by Lehr and Antopol.[21] It is usually not difficult to demonstrate crystalline depositions in tubular structures in frozen section preparations of kidney tissue. Passage of kidney sections through the various steps of the paraffin technique followed by hematoxylin-eosin staining dissolves out the sulfonamide crystals. Museum specimens of kidneys, ureters, and urinary bladders soon become worthless due to the fact that crystalline deposits of these drugs slowly dissolve in the Kaiserling solutions.

It was our privilege recently to examine the kidneys, ureters, and urinary bladder of a monkey which had died from an infectious disease. In treating the infection the animal had received large doses of sulfapyridine. At autopsy a large amount of crystalline material was found in the bladder and both ureters were completely blocked (Fig. 5) by crystal accumulations resulting in extensive bilateral hydronephrosis, undoubtedly hastening the animal's death. Excellent discussions of urinary tract changes are found in the articles by Winsor and Burch[22] and Antopol, Lehr, Churg, and Sprinz.[23]

Grass, Cooper, and Morningstar[24] have produced the experimental lesions of glomerulonephritis in rats with sulfapyridine. The lesions reported consisted of swelling and proliferation of the capsular epithelium, basement membrane thickening, hyaline degeneration of the tufts, endothelial proliferation of the tuft vessels, and adhesions of the tufts to Bowman's capsule.

Grave disturbances in the hematopoietic system may be encountered in sulfonamide therapy. This may take the form of a rapidly fatal acute hemolytic anemia, a fatal agranulocytosis, or less serious manifestations of these diseases. In the instances of agranulocytic angina, it is likely that these drugs may act in a manner similar to certain barbiturates, such as amytal, barbital, dial, or neonal. These are all "coal tar" derivative or "benzene ring" drugs, similar to the sulfonamides, and have a markedly depressing effect in some patients upon the leucoblastic centers in the bone marrow. It is needless to say that frequent leucocyte and erythrocyte counts and hemoglobin determinations during the course of therapy will forestall in many cases these serious complications. Spring and Bernstein,[25] Jennings and Southwell-Sander,[26] and many others report important findings from the hematologic standpoint in these cases.

An important lesion which is too infrequently mentioned is interstitial myocarditis. A review of the literature reveals the fact that attention is focused solely upon lesions of the kidneys, skin, liver, and hematopoietic system. It is very likely that changes in the myocardium have been overlooked in human autopsy material and also in experimental animals. It is hoped that the few articles appearing on interstitial myocarditis in patients receiving the sulfonamide drugs will stimulate further interest in this much neglected topic.

Our interest in interstitial myocarditis was occasioned by a perusal of the experimental work and autopsy study of human hearts by French and Weller.[27] We have noted histopathologic findings in human hearts similar to those reported by these authors. These consisted of eosinophilic cellular infiltrations between the muscle fibrils (Fig. 6), and in some cases forming collars about the small branches of the coronary vessels (Fig. 7). The cells were mainly large

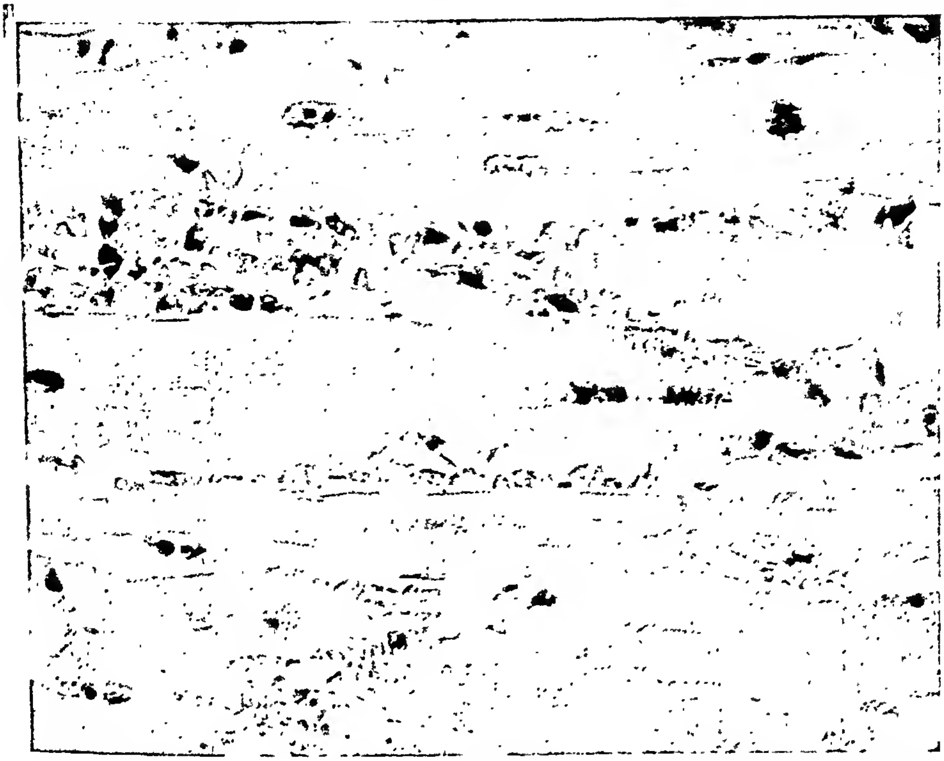

Fig. 6.—Photomicrograph of section of human heart showing interstitial accumulations of blood cells. Most of these cells are large mononuclears with pink staining cytoplasm. There are present also some neutrophiles and a few erythrocytes. (×550.)

Fig. 7.—Photomicrograph of heart section showing perivascular infiltration with cells of a type similar to those described in Fig. 6 (×400.)

mononuclear cells with pink-staining cytoplasm and a considerable number of polymorphonuclear leucocytes, many with an eosinophilic cytoplasm.

In the study by French and Weller 126 cases, or 44.5 per cent, of the 283 receiving sulfonamide drugs showed a significant interstitial myocarditis. While the series studied by us so far is small, it probably will not reveal as high a percentage of interstitial myocarditis as reported by French and Weller.[27] In not any of our cases could the characteristic eosinophilic infiltrations be attributed to any other agent or cause than the sulfonamides.

Electrocardiographic changes were noted in a series of patients receiving these drugs, as reported by Scheinberg, and Ingle,[28] and Dazzi.[29]

In passing it might be appropriate to mention a word about the large number of deaths which followed the use of elixir of sulfanilamide in September and October of 1937. This whole matter is excellently reviewed in a Special Article[30] in the *Journal of the American Medical Association*. It should be re-emphasized that sulfanilamide was not to blame for these deaths, but its vehicle, diethylene glycol, a highly poisonous substance was responsible.

The tremendous popularity of the sulfonamides is shown by referring to the statistics of Drug Trade News, as quoted by Pruitt.[31] The manufacturers' sales in the United States in 1940 of sulfanilamide alone amounted to 543,802 pounds. What percentage of this was disposed of on physicians' prescriptions is difficult to say. The danger of the indiscriminate use of these drugs was pointed out in an Editorial[32] by the *Journal of the American Medical Association* as far back as 1937: "The startling news reports that the administration of sulfanilamide will 'cure' gonorrhea in forty-eight hours has led to some unpleasant results. Responsibility lies considerably with pharmacists who are willing to sell dangerous drugs to anybody over the counter. In one large city, hospitals have admitted young men with severe sulfhemoglobinemia resulting from self-medication with sulfanilamide. The physician must bear in mind the potential hazards of this drug."

CONCLUSIONS

A study of a large series of cases and a careful review of the literature reveals the important finding that any organ or tissue in the body may be affected through the toxic action of the sulfonamides. In what percentage of cases this occurs is impossible to say. Considering the popularity of these drugs and the tremendous quantity used, amounting to over one-half million pounds of sulfanilamide for 1940 alone, it is not surprising to note some bad effects and even deaths from time to time.

The immediate effects of these drugs upon the skin, liver, kidneys, and nervous system is well understood. It is not possible at this time to say what residual effects may be noted in the myocardium, liver, or other organs years later. Might such changes lead to chronic myocarditis or cirrhosis of the liver? Might they lead to bizarre blood dyscrasia? No one as yet knows the answer.

Greater precaution in the use of these drugs is advisable. Dispensing on physicians' prescriptions only would lead to proper control and discourage abuse and indiscriminate use by the laity. It is certainly not the intent to discourage a drug which has proved its merit. At times, as in grave pneumonias, meningitis, puerperal infections, and otherwise serious bacteriemias it may truly be a "life-

saver." In cases of less gravity or in disease entities in which other therapy may be employed its usefulness is doubtful.

When sulfonamide therapy is indicated and necessary, certain precautions should be observed which may prevent disastrous effects from the toxicity of the drug. The amount of drug and duration of administration should be kept at a minimum consistent with beneficial results. Frequent checking to determine proper concentration of the drug in the blood is essential. Frequent erythrocyte and leucocyte counts and hemoglobin determinations with an immediate discontinuance of medication when there is evidence of important changes in these elements. An evaluation of renal function is necessary because a damaged kidney handles these drugs poorly. Progressive oliguria and hematuria may make continued administration of the drug hazardous. A continued high temperature after other signs of infection have disappeared may be entirely due to the drug. In a number of such cases observed the temperature has dropped to normal following the discontinuance of the sulfonamides. Alkalinization may prevent renal calculus formation. Electrocardiographic tracings may shed light on early myocardial changes following the use of these drugs.

An agent which is toxic for bacteria may in many instances be equally as toxic for the cells of the host and thereby increase the burden rather than lessen it. The normal tissues of the control animal, employed by the pharmaceutical firms, are affected to a lesser extent than the tissues and organs of a sick patient already the seat of cloudy swelling, fatty degeneration, etc., the result of bacterial toxemia.

Undoubtedly, with a check on the injudicious use of the sulfonamides, their discontinuance in diseases wherein the mortality is nil and where other forms of therapy are effective and close observation of the patient in whom their use is thought to be of decided benefit will result in fewer serious reactions and possible death.

INFESTATION WITH STRONGYLOIDES STERCORALIS*

M. B. Levin, M.D., Baltimore, Md.

Human infestation with *Strongyloides stercoralis* in the Middle Atlantic states has been distinctly uncommon.[1] Infested persons in this section of the United States were usually carriers in whom original infestation was traceable to a sojourn in subtropical or tropical regions. Since infestation usually occurred by cutaneous or oral contact with stool from a carrier, it is reasonable to believe that cases occurred in persons who journeyed out of northern climates.

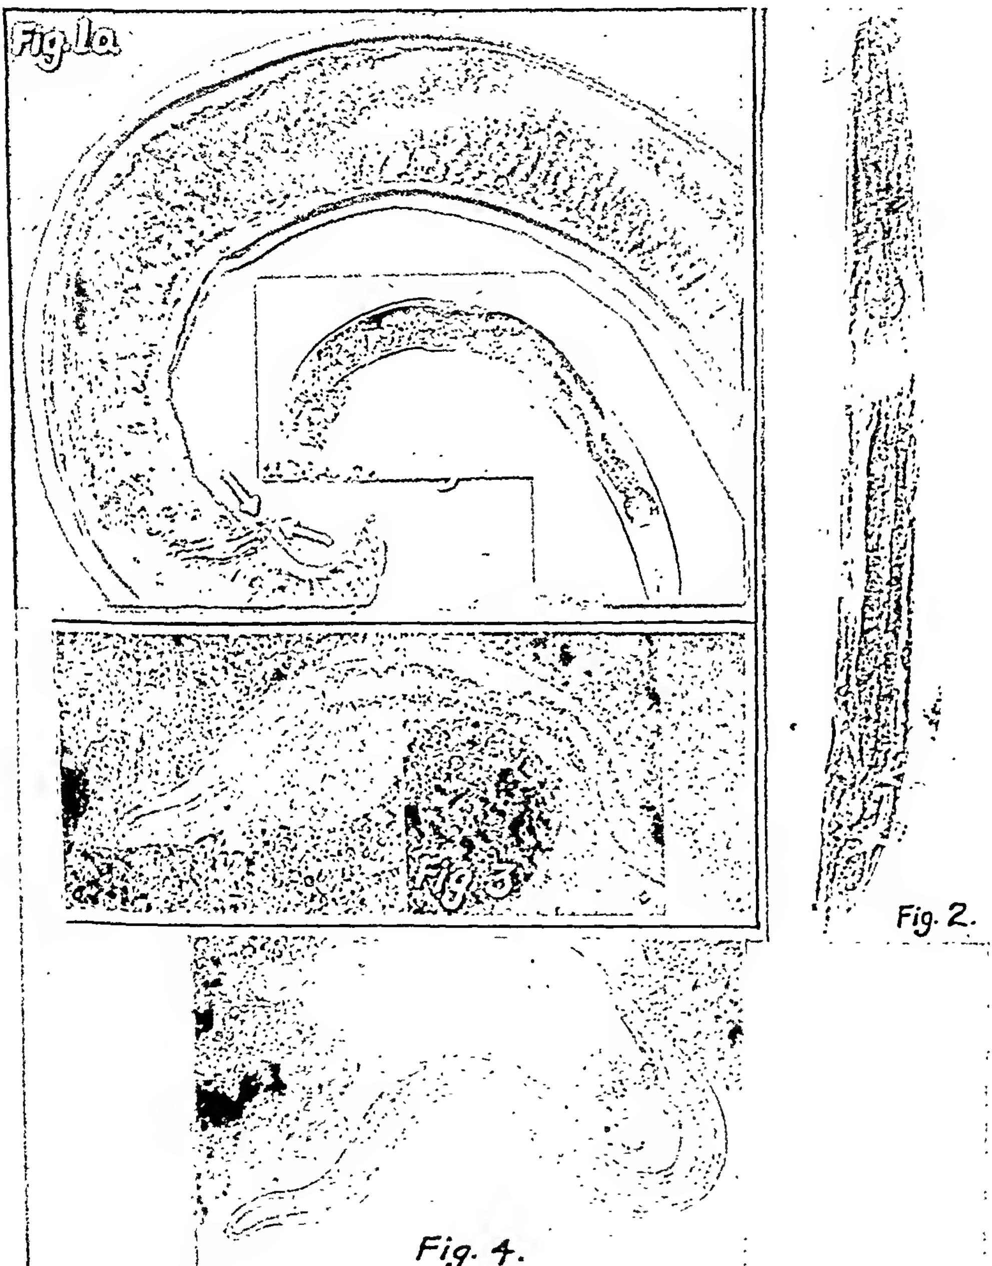
We were fortunate in having secured stool containing *Strongyloides stercoralis* larvae from a patient who had always lived in Maryland, except for a short visit to Virginia about twenty years ago. This case was of interest because the patient's infestation undoubtedly occurred in a nontropical region,

*The Burton-Levin Foundation, Inc.
Received for publication, July 21, 1942.

presumably from infested material from a carrier; and because of the opportunity presented of photographing the rarely observed and only recently discovered male form of the parasite.[2]

ABSTRACT OF REPORTED CASE

The patient presented no definite symptoms of *Strongyloides stercoralis* infestation and only a few very vague gastrointestinal complaints, such as flatu-



Figs. 1-4.—*Strongyloides stercoralis*, adult male and male and female larval forms.

lence, pyrosis, and constipation. He was a 51-year-old policeman who showed during the past year some anginal symptoms that were relieved by belching and morphine; his blood picture revealed a 6 per cent eosinophilia and a mild secondary anemia; and his electrocardiographic findings indicated some myocardial damage. Examination of the stool showed numerous *Strongyloides stercoralis* larvae which was the chief point of interest in this case.

DISCUSSION

In Fig. 1*a*, ×430 magnification, the male sexual organ of the adult form of *Strongyloides stercoralis was plainly seen.* The copulatory spicules and gubernaculum were indicated. In Fig. 1*b*, ×100 magnification, the fertilizing element of the male adult form was indicated at the exit of the sexual organ. Fig. 2, ×430 magnification, showed the male larva with the immature sexual organ indicated. In Fig. 3 and Fig. 4, ×430 magnification, the female larval forms of the parasite were indicated.

SUMMARY

A case is reported in which (1) infestation of *Strongyloides stercoralis* parasites was contracted in a relatively northern region; and (2) the rarely observed male larval and adult form of the *Strongyloides stercoralis* was found in the stool.

THE EFFECT OF CINCHOPHEN ON BILE FORMATION*

A. L. Berman, E. F. Snapp, A. J. Atkinson, and A. C. Ivy
Chicago, Ill.

On the basis of the results of duodenal drainage experiments it has been reported that cinchophen is a choleretic in man.[1] In the anesthetized dog the drug has a very definite choleretic action[2]; it has no choleretic action in the rabbit.[3, 4] The effect of a single dose or repeated doses in the chronic biliary fistula preparation has not been studied. It was considered important to perform such an experiment because the drug, at least in large doses, is considered to be an hepatotoxic agent.[5]

METHODS

Five healthy biliary fistula dogs which had been carefully observed under dietary control for from two to three months were used. The bile was collected

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.

by the Rous-McMaster technique, except as otherwise stated. Three types of experiments were performed: (A) The animals were placed on a control period for from three to five days, the standard diet being fed twice daily without the return of bile or the administration of bile salts or drug. The volume output, and the cholic acid, cholesterol, and total pigment outputs were determined daily. Then the animals were given 1 Gm. of cinchophen in 0.5 Gm. doses with the meal for three days. The cinchophen used was the "pure," or snow white cinchophen prepared by the Calco Company, and was completely soluble in alkaline aqueous solution and devoid of odor; it is less toxic and a different product than that yellowish white product marketed several years ago.[12] The determinations made during the control period were repeated during the test period. However, cinchophen excretion in the bile every twenty-four hours was determined by the method of Bradley.[2] The diet consisted of a commercial dog food (Pard) which was supplemented with dried yeast and cod-liver oil, the dogs consuming the same amount of the diet daily. (B) The second type of experiment consisted in giving cinchophen as above, except it was given for a period of fourteen days. (C) The third type of experiment consisted of giving cinchophen and then returning all bile formed every hour. The detailed method will be given later.

RESULTS

A. The Effect of Cinchophen Administration for Three Days.—On the average, 1 Gm. of cinchophen daily, given as two doses of 0.5 Gm. with the morning and evening meal, increased the volume output of bile over the control by 106 per cent (Table I). The range of increase was from +77 to +136 per cent above the control output. The bile was clear and odorless, and at no time resembled the bile obtained in the presence of an infectious hepatitis. The choleresis pro-

duced was analogous to that obtained with 3 Gm. of dehydrocholanic acid salts (ketochol) or of sodium dehydrocholate (decholin, sodium).[7]

On the average *cholic acid synthesis* was not changed, although the individual tests show a range of from −19 to +16 per cent. A plus or minus range of 10 to 15 per cent occurs in some groups of dogs, however, under apparently constant environmental conditions. The *total pigment output* showed a +18 per cent increase on the average; it was increased or not altered in all but three tests, which is not a significant increase according to our previous observations[7, 8] on this type of biliary fistula preparation, in which a variation of + or −25 per cent of the mean may occur. A definite increase in *cholesterol output* occurred. The output of cholesterol, however, is increased when a choleresis is produced by the administration of conjugated ox bile acids or the return of dog's bile. According to our observations,[7] the cholesterol output varies + or −20 per cent under constant environmental conditions.

From 61 to 75 per cent of the cinchophen administered was recovered in the twenty-four-hour volume of bile. This agrees with the observations of Bradley and Ivy,[2] who recovered from 59 to 78 per cent in semiacute biliary fistula dogs. The test for cinchophen was negative in the precontrol and postcontrol cinchophen period.

Comment: It is clear from the results that cinchophen administered in 0.5 Gm. doses with the meals to the 5 dogs used produced no evidence of toxicity, using volume output, cholic acid synthesis, pigment, and cholesterol output as criteria. It is possible, however, that a period of three days of administration is not sufficiently long to produce hepatotoxic signs.

B. The Effect of Cinchophen Administration for Fourteen Days.—Following the same procedure as in the experiment above, 1 Gm. of cinchophen was given daily for fourteen days.

Dog 5 had suffered a partial obstruction of the bile duct several days prior to the start of the control period. We decided to use the animal to ascertain what might happen when cinchophen is administered during a time that the liver is recovering from an obstruction. During the obstruction the bile had a bad odor and was infected. This tended to clear when the obstruction was relieved.

TABLE II

THE EFFECT OF 1 GM. OF CINCHOPHEN DAILY FOR FOURTEEN CONSECUTIVE DAYS ON CHRONIC BILIARY FISTULA DOGS, NO BILE OR BILE SALT BEING GIVEN

*See Table III.
†Cinchophen given for thirty-three days.

The results obtained from six experiments on the 5 dogs are shown in Table II. The results are approximately the same as those obtained in the three-day experiment.

In Dog 83, the second test on the dog recorded in Table II, cinchophen was administered for thirty-three days. During this period the animal consumed all his diet with appetite, though no bile was returned or bile salts were administered. The animals as well as the composition of the bile remained normal. The average volume output during the last eleven days was 254 c.c. per day, and the average cholic acid synthesis was 1,336 mg; both tended to be higher than during the earlier part of the experiment. It should be remarked that other dogs may synthesize and excrete less cholic acid during the first than during the second week.

Average						255	718	27.0	121.7

*An obstruction of the bile duct was relieved three days before the start of this experiment. The low cholic acid output during the first few days is attributable to an hepatitis. The animal consumed all the diet each day.

No bile was returned; no bile salts were given.

The results on Dog 5 are of particular interest because the dog had not fully recovered from a partial biliary obstruction and hepatitis when cinchophen medication was started. The daily determinations are recorded in Table III. At the start of the experiment only 0.3 to 0.4 Gm. of cholic acid was synthesized daily. Later, cholic acid output increased to 0.8 to 0.9 Gm. daily.

Comment: On the basis of the criteria used, the administration of 1 Gm. of cinchophen daily, 0.5 Gm. with each meal, for fourteen days and in one case for thirty-three days caused no evidence of hepatic injury.

In the dog recovered from partial obstruction and hepatitis, the liver manifested a gradual recovery. Whether the recovery of the animal was retarded cannot be stated, since such animals in our experience may recover in from three to fourteen days when no cinchophen is given. However, in such instances we always give a bile salt preparation or return bile with the idea of flushing the ducts, since obstruction, as a rule, occurs in our dogs only when they are kept on food without bile salts or the return of bile. The thick bile formed in the absence of the return of bile or bile salts definitely favors obstruction and infection

of the bile; this is the chief reason why we never deprive our dogs of bile for a longer period than from five to seven days, except when we give them some other choleretic.

The fact that no cinchophen could be found in the bile twenty-four hours after the last dose was given shows that it is rather rapidly excreted or metabolized. The fact that we were able to obtain from 61 to 75 per cent of the administered cinchophen in the bile shows that cinchophen in the presence of an intact biliary tract may undergo repeated enterohepatic circulation. Since in our dogs the cinchophen given could undergo only one enterohepatic circulation, *it is possible that hepatic injury may occur in the intact animal due to repeated enterohepatic circulation.* This hypothesis was tested by the following experiment.

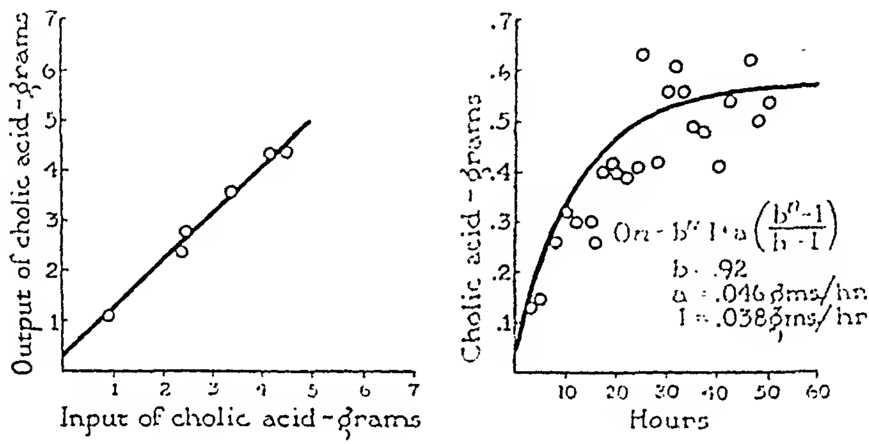

Fig. 1.

C. *The Effect of Repeated Enterohepatic Circulation of Cinchophen in the Dog.—Method.* One biliary-duodenal fistula "suction" dog[9] was used. The dog weighed 9.0 kg. The bile was collected in a glass cylinder and could be returned directly into the intestine through the duodenal fistula. The animal was fed at eight-hour intervals one-third of his daily ration of the standard diet. The bile was collected and returned on an hourly schedule, the volume being recorded and a 0.1 c.c. sample being retained for cholic acid assay. The bile collected hourly was returned to the intestine during a five- to ten-minute period for forty-eight hours. After a three-day control period of no return of bile the hourly return was started and 333 mg. of cinchophen was mixed with each eight-hour feeding.

Results. It has been shown previously[10, 11] that when bile is returned to an animal every hour after a period during which no bile has been returned, the cholic acid output, due to enterohepatic circulation, will increase according to a definite curve or formula and will in time reach a relatively constant or homeostatic level, at which synthesis is balanced by the "destruction" of cholic acid. In view of this fact, it was thought that if cinchophen disturbed cholic acid synthesis, the disturbance would result in a modification of the "normal" curve of accumulation. Therefore, the data obtained on cholic acid output on the hourly return of bile with cinchophen administration was treated mathematically as in previous work.[10, 11]
